1. The LHC and the CMS detector

1.1 The Large Hadron Collider

The LHC [1] is currently the largest and the most powerful particle accelerator ever built. It is installed in the 26.7 km tunnel that was originally constructed for the LEP accelerator in the 1980s. The tunnel lies at a depth of 45 m to 170 m underground between the Jura mountain and Lake Geneva, being the main part of the CERN accelerator complex.

The machine is designed to accelerate proton beams and provide collisions at a centre of mass energy of $\sqrt{s} = 14$ TeV. Unlike particle-antiparticle colliders, the LHC requires two rings with opposite magnetic dipole fields in order to maintain and collide two counter-rotating proton beams. Since the tunnel was originally designed for the electron-positron LEP, it has an internal diameter of 3.7 m which is not enough to install two separate independent rings. Therefore, a twin-bore magnet design was adopted [2], which resulted in substantial cost savings.

Figure 1.1: CERN accelerator complex.

A schematic view of the LHC accelerator chain is shown in Figure 1.1. Initially, the protons are obtained by stripping orbiting electrons from hydrogen atoms. Then they are injected into the linear accelerator LINAC2 to reach the energy of 50 MeV and enter the Proton Synchrotron Booster (PSB). The booster accelerates them to 1.4 GeV and passes the beam to the Proton Synchrotron (PS) where the energy rises to 25 GeV. In the next step, protons enter the Super Proton Synchrotron (SPS) where they are accelerated to 450 GeV. Finally, the beam is transferred to the LHC in both clockwise and anti-clockwise directions where it takes about 20 minutes to reach the design 7 TeV energy (per beam).

[add the number of magnets, total energy stored, number of bunches, bunch spacing etc.?)

The LHC has four interaction points, providing collisions to four major experiments. Two of them, CMS and ATLAS, are multi-purpose high-luminosity experiments with a peak luminosity of $L = 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$. The other two experiments operate at low luminosities and have more specific physics goals: LHCb studies b-meson decays, and Alice is a dedicated heavy ion experiment.

The instantaneous luminosity of a collider can be calculated as

$$L = \frac{n_1 n_2 f}{4\pi \sigma_x \sigma_y}, \quad (1.1)$$

where n_1 and n_2 are the numbers of particles in each of the colliding bunches, f is the revolution frequency, σ_x and σ_y are the horizontal and vertical beam sizes, assuming the two beams have the same size.

The number of events generated in the collisions per second is given by

$$N_{events} = L \times \sigma, \quad (1.2)$$

where σ is the cross section of the process under study.

[add the plots with cross sections and production rates?)

The LHC started operating on the 10th of September 2008, with the first beams fully circulating in both rings. However, only 9 days later a magnet quench occurred in two sectors of the tunnel, which was caused by an electrical fault due to a bad connection between two magnets. A consequent liquid helium explosion damaged a total of 53 superconducting magnets. Over a year was spent on repairs and tests, and the first collisions were recorded on the 23rd of November 2009 at a centre of mass energy of 0.9 TeV. The following few months showed the continuous ramp up of the beam energies up to 3.5 TeV per beam which was achieved on the 30rd of March 2010 when the LHC physics programme started.

Throughout the rest of 2010, the two general-purpose LHC experiments (CMS and ATLAS) recorded approximately 40 pb^{-1} of data, which resulted in the first measurements of various physics processes at the LHC. The following year became the main 7 TeV data-taking period, with about 5 fb^{-1} of data recorded by ATLAS and CMS. On the 5th of April 2012 the centre of mass energy was increased to 8 TeV, and July of 2012 marked the first major discovery of a new boson which was later shown to be consistent with the Standard Model Higgs boson, according to approximately 21.8 fb^{-1} of data recorded until early 2013. A long shut-down is planned for the following two years with various upgrades scheduled. The next physics run is expected in 2015 with the beam energy increased up to 6 or 7 TeV.

[add any upgrade details and distant future plans, like SLHC?]

1.2 The CMS Detector

The Compact Muon Solenoid [3] is a general-purpose detector designed to carry out precise measurements of the Standard Model and searches for physics beyond it. The primary design requirement was the ability to discover the nature of electroweak symmetry breaking, and the first observation of a Higgs boson was obtained in the Summer of 2012 [4].

The detector is installed at one of the LHC interaction points (Point 5) at about 100 m underground near the French village of Cessy, between the Jura mountains and Lake Geneva. The overall dimensions of the CMS detector are a length of 21.6 m, a diameter of 14.6 m and a total weight of 12 500 t.

The sectional view of CMS is shown in Figure 1.2. In the centre of the detector, tracking and calorimetry systems are surrounded by the superconducting solenoid. On the outermost part of it the magnetic flux is returned through the iron yoke in which the muon system is also integrated. All the sub-systems are discussed in the following sections in more detail.

The cylindrical shape of the CMS detector dictates using a cylindrical coordinate system, with the origin centred at the interaction point, the x -axis pointing towards the centre of the LHC ring, the y -axis pointing upwards and the z -axis pointing along the beamline in the anti-clockwise direction. The azimuthal angle ϕ is measured from the x -axis in the transverse ($x - y$) plane and the polar angle θ is measured from the z -axis. The radial distance to the beamline is denoted by r . Pseudorapidity is defined as:

$$\eta = -\ln \tan \frac{\theta}{2}. \quad (1.3)$$

This implies that the particles moving in the transverse plane (perpendicular to the beamline) have a pseudorapidity of 0, whereas the beam direction has an infinite pseudorapidity.

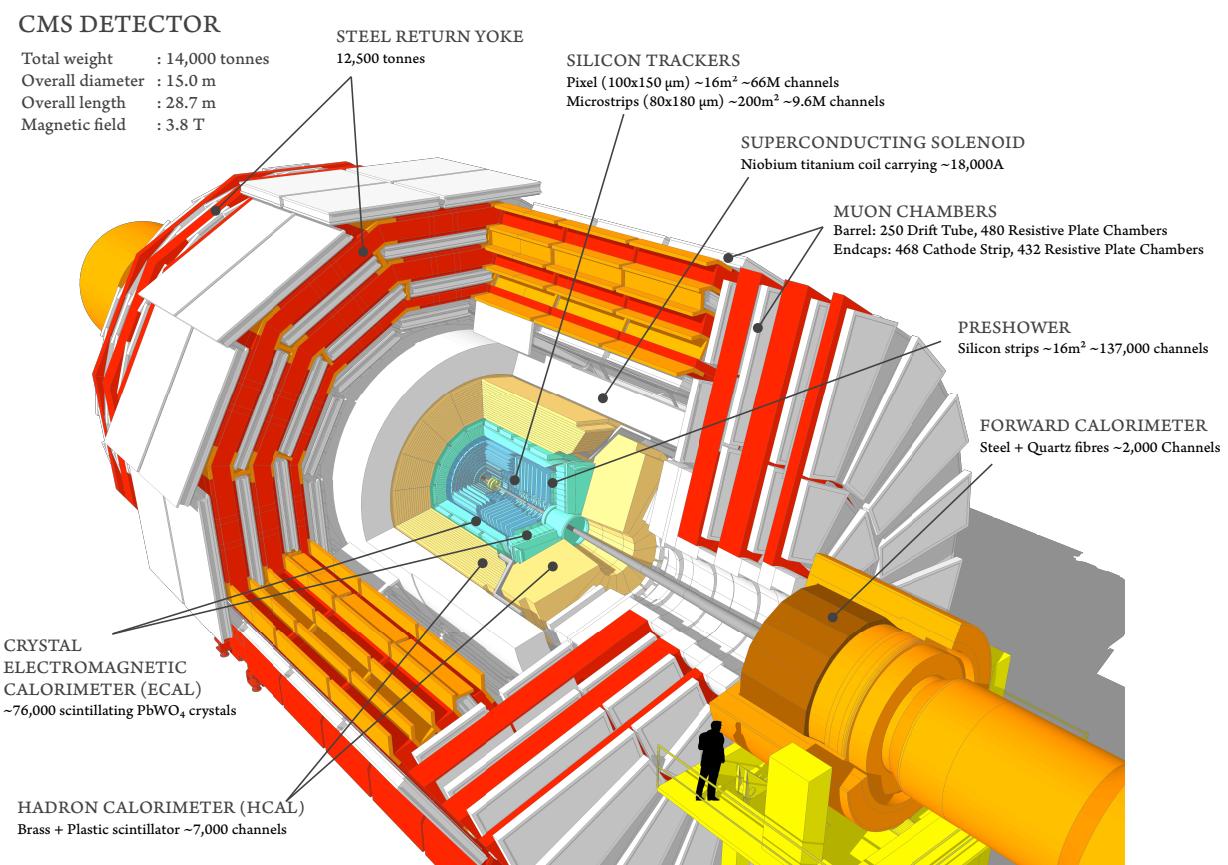

Figure 1.2: Sectional view of the CMS detector.

Considering the cylindrical shape of the detector, it has barrel and endcap regions, with the transition occurring at $\eta \sim 1.4$. The momentum and energy transverse to the beamline are denoted by p_T and E_T respectively; the imbalance of the energy measured in the transverse plane, called missing transverse energy, is denoted by E_T^{miss} .

1.2.1 Inner Tracking System

The tracking system lies in the heart of the CMS detector and is the closest to the interaction point where the particle flux has the highest value. This imposes demanding requirements on the configuration of the system. At design luminosity of $L = 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ with the bunch spacing of 25 ns, an average of 1000 particles from about 25 proton-proton interactions (pile-up vertices) is expected to traverse the tracker for each bunch crossing. However, up until the long shutdown a bunch spacing of 50 ns was used, which meant a higher number of protons in each bunch leading to approximately twice the number of pile-up vertices. Therefore, in order for the particle tracks to be identified reliably and separately for each bunch crossing, the tracker requires very fine granularity and fast response parameters. Another complication caused by the intense particle flux is the severe radiation damage, so the tracker has to be highly resilient in operating in the harsh environment for a reasonable lifetime.

To meet these requirements on granularity, response time and radiation resilience, the tracker design was chosen to be based on silicon detector technology. Although capable of meeting such conditions, this technology has a disadvantage of a high power density of on-detector electronics. This implies the necessity of an efficient cooling system. Moreover, a large amount of dense material interacting with the particles leads to higher multiple scattering, bremsstrahlung, photon conversions and nuclear interactions. Therefore, there are complications in the reconstruction of the tracks, meaning some loss of efficiency and precision. This will be discussed in detail later on in the object reconstruction section.

Figure 1.3 shows the overall layout of the tracking system. It consists of the inner pixel detector, located in the vicinity of the interaction point, and silicon strip tracker detectors: inner barrel and disks (TIB and TID), outer barrel (TOB) and endcaps (TEC). The geometrical acceptance of the tracker system goes up to $|\eta| < 2.5$. The outer radius of the CMS tracker reaches approximately 110 cm, and its total length is about 540 cm.

The pixel detector consists of three layers of pixel sensors at radii of 4.4 cm, 7.3 cm and 10.2 cm from the beamline in the barrel region. In addition there are two endcap disks on each side at $|z| = 34.5$ cm and 46.5 cm. The pixel size equals $100 \times 150 \mu\text{m}^2$ in $r\phi \times z$ coordinates. The pixel detector has 66 million pixels and the total area of about 1 m².

Figure 1.3: Cross-section of the CMS tracker system [3].

The silicon strip tracker consists of several layers of silicon microstrip detectors. It covers the region between 20 cm to 110 cm in radius and extends up to ± 280 cm in the z direction. The Tracker Inner Barrel (TIB) is made out of 4 layers and the Tracker Outer Barrel (TOB) has 6 layers in it. The tracker endcaps (TEC) comprise 9 disks, and there are also the tracker inner disks (TID) that consist of 3 disks filling the gap between TIB and TEC as shown in Figure 1.3. There are 9.3 million silicon strips covering the area of about 200 m^2 . The silicon sensors' thickness varies between 320 and 500 μm and the strip pitch varies from 80 μm in the TIB to 180 μm in TOB and TEC.

The silicon detectors of the tracker, the readout electronics and support structure form a considerable amount of material for the particles traversing from the interaction point. Figure 1.4 [3] shows the material budget of the CMS tracker in units of radiation lengths¹ (X_0). It grows from about $0.4 X_0$ to $1.8 X_0$ in the barrel region, and then decreases to about $1 X_0$ in the endcaps. This causes a substantial conversion rate for photons and electrons in the tracker material; it also will be discussed in more detail in the electron reconstruction section.

[perhaps need to add the p_T resolution plots]

¹A material's radiation length is the mean distance over which a high-energy electron loses all but $1/e$ of its energy by bremsstrahlung; this is equal to $7/9$ of the mean free path for pair production by a high-energy photon.

Figure 1.4: Material budget as a function of pseudorapidity η for the different sub-detectors of the tracker (left) and broken down into the functional contributions (right), in units of radiation length [3].

1.2.2 Electromagnetic Calorimeter

The next detector subsystem which is surrounding the tracker is the electromagnetic calorimeter, or ECAL. It is of a primary importance for the analyses described in this thesis, as it provides information for the electron and positron reconstruction. Combination of this information with that from the tracking system must ensure a precise measurement of electron position and momentum, and also sufficient background removal. It has to effectively distinguish the energy deposit shape of an electromagnetic particle from the one of a hadronic particle, which requires good segmentation and high resolution.

ECAL is a hermetic, high-granularity, high-resolution scintillating crystal calorimeter consisting of 61 200 lead tungstate (PbWO_4) crystals located in the central barrel region ($|\eta| < 1.479$), and 7324 crystals in each of the two endcaps ($1.479 < |\eta| < 3.0$). All crystals are followed by photodetectors reading and amplifying their scintillation: avalanche photodiodes (APD) are used in the barrel, and vacuum phototriodes (VPTs) are used in the endcaps. These different choices were caused by the configuration of the magnetic field and the expected level of radiation.

The layout of the ECAL sub-detector is shown in Figure 1.5. An additional preshower detector is used in the endcap region to lower the required detector depth. Its principal

Figure 1.5: Layout of the CMS electromagnetic calorimeter [3].

aim is to identify neutral pions in the endcaps, but it also helps to distinguish neutral pions and electrons from minimum ionising particles and improves the position determination of electrons and photons with high granularity.

Table 1.1: ECAL crystal characteristics

	Barrel	Endcaps
number of crystals	61 200	14 648
crystal cross-section in (η, ϕ)	0.0174×0.0174	varies
crystal cross-section at the front	$22 \times 22 \text{ mm}^2$	$28.62 \times 28.62 \text{ mm}^2$
crystal cross-section at the rear	$26 \times 26 \text{ mm}^2$	$30 \times 30 \text{ mm}^2$
crystal length	230 mm ($25.8X_0$)	220 mm ($24.7X_0$)

The main geometrical characteristics of the ECAL crystals are shown in Table 1.1. The choice of lead tungstate was driven by the constraints of the CMS design. It is a very dense material (8.28 g/cm^3) with a short radiation length of $X_0 = 0.89 \text{ cm}$, which allows the calorimeter to fit inside the compact magnet. Lead tungstate also has a small Molière radius¹ of 2.2 cm, which allows a calorimeter with fine granularity. Finally, the crystals emit 80 % of their scintillation light in just 25 ns, however the light yield is relatively low. At 18°C , about 4.5 photoelectrons per MeV are collected. The dependence of the light yield on temperature requires a cooling system capable of keeping the crystal temperature stable within $\pm 0.05^\circ\text{C}$ to preserve energy resolution [5].

The energy-dependent resolution of the calorimeter can be parameterised as follows [3]:

$$\left(\frac{\sigma}{E}\right)^2 = \left(\frac{S}{\sqrt{E}}\right)^2 + \left(\frac{N}{E}\right)^2 + C^2. \quad (1.4)$$

where S is the stochastic term, N is the noise term, and C is the constant term. Figure 1.6 shows the energy resolution measured using incident electrons, during the beam tests in 2004.

1.2.3 Hadron Calorimeter

The hadron calorimeter (HCAL) is the next sub-detector located mostly inside the solenoid and completing the CMS calorimetry system. It is essential for the measurement of

¹The Molière radius R_μ is a characteristic constant of a material giving the scale of the transverse dimension of the fully contained electromagnetic showers initiated by an incident high energy electron or photon. It is defined as the radius of a cylinder containing an average of 90 % of the shower's energy deposition.

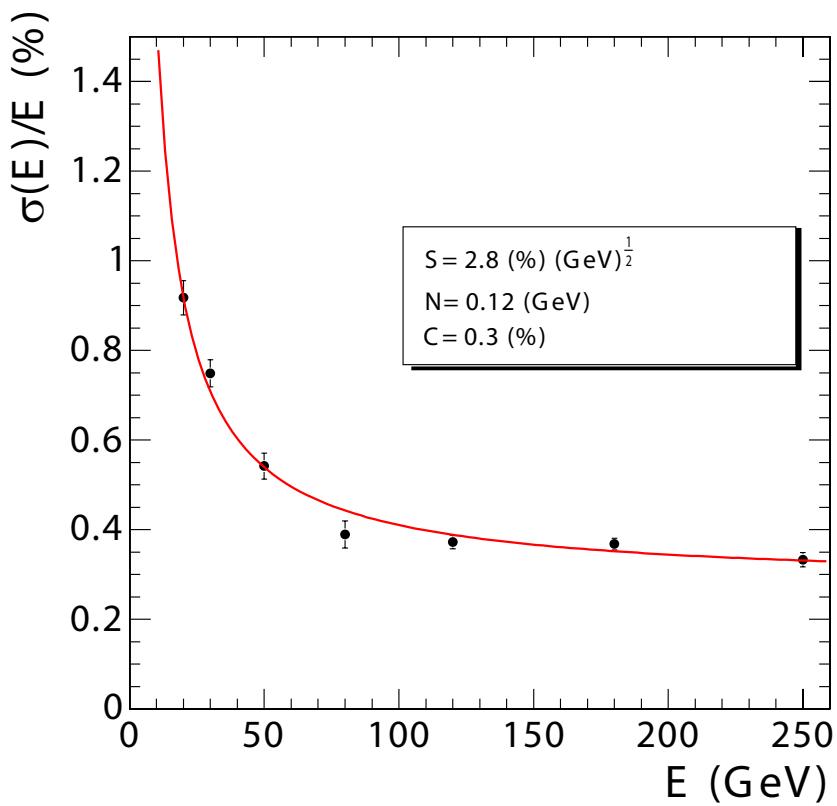

Figure 1.6: ECAL energy resolution derived from the test beam measurements as a function of deposited energy. The stochastic, noise, and constant contributions are shown [3].

hadron jets and missing transverse energy.

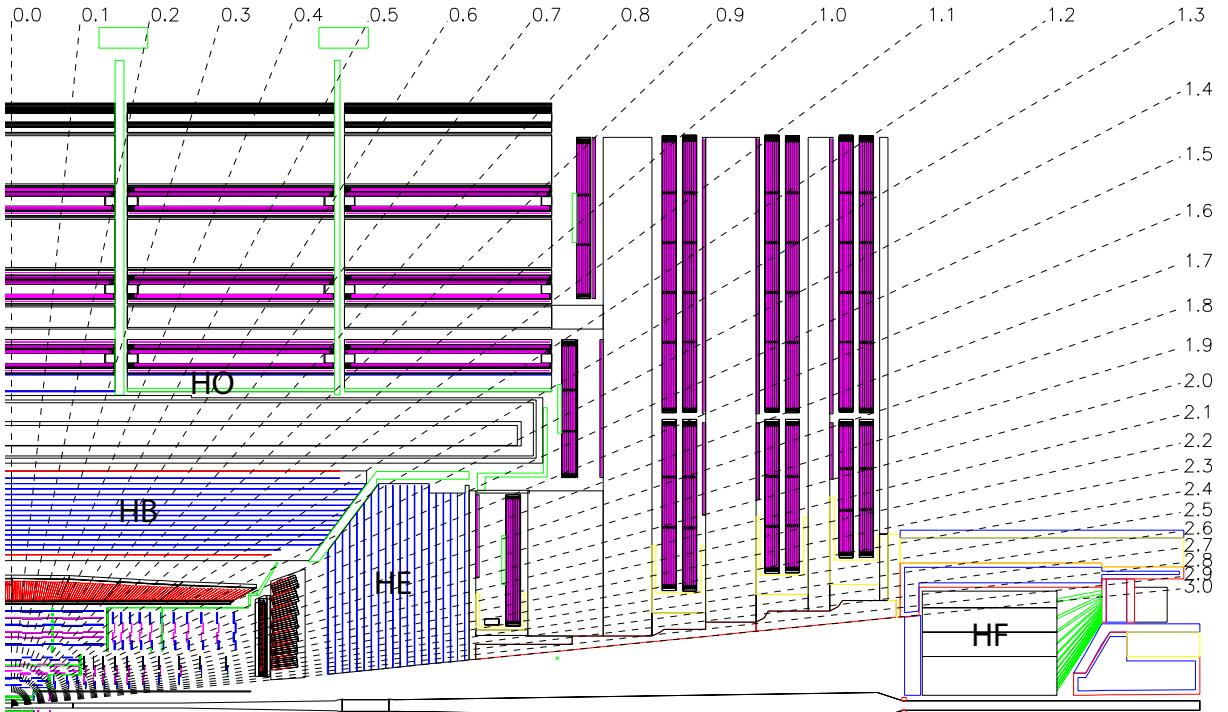

Figure 1.7: Longitudinal view of the CMS detector showing the locations of the hadron barrel (HB), endcap (HE), outer (HO) and forward (HF) calorimeters [3].

As shown in Figure 1.7, HCAL consists of four subsystems: the hadron barrel calorimeter (HB), the hadron endcap calorimeter (HE), the hadron outer calorimeter (HO) and the hadron forward calorimeter (HF). The barrel and endcap parts (HB, HE) cover the pseudorapidity range up to $|\eta| < 3.0$, and the forward part (HF) extends it to a total coverage of $|\eta| < 5.0$. HCAL surrounds ECAL from its outer limit of 1.77 m from the beamline, to the inner limit of the magnet coil at 2.95 m from the beamline. However, due to space limitations the barrel calorimeters do not contain complete hadronic showers, therefore an outer calorimeter (HO) was designed to measure the energy leakage. It is placed in the muon system just outside of the solenoid in the barrel region.

HCAL is a sampling calorimeter consisting of alternating layers of brass and stainless steel absorbers, and plastic scintillators as active elements. The choice of the absorber material was caused by its short hadronic interaction length and its property of being non-magnetic, which is crucial in the strong magnetic field of the CMS magnet. The scintillation light is guided by embedded wavelength-shifting (WLS) fibres. The light from the WLS is then

transmitted via a network of clear fibres, arranged in read-out towers, to hybrid photodiodes (HPDs) [3].

Both HB and HE scintillators have a granularity of $\Delta\eta \times \Delta\phi = 0.087 \times 0.087$ for $|\eta| < 1.6$, and $\Delta\eta \times \Delta\phi = 0.17 \times 0.17$ for $|\eta| \geq 1.6$. The tower segmentation of the forward calorimeter (HF) varies from $\Delta\eta \times \Delta\phi = 0.175 \times 0.175$ at $|\eta| = 3.0$ to $\Delta\eta \times \Delta\phi = 0.3 \times 0.35$ at $|\eta| = 5.0$. The HF is placed at about 11 m from the interaction point, and is essential to reconstruct very forward hadron jets. Together with HO, it provides the hermeticity of the calorimetry system, making it possible to measure the transverse missing energy to a reasonable precision.

[perhaps need to add the energy resolution plots]

1.2.4 Superconducting Magnet

The superconducting solenoid is a central feature of the CMS apparatus, essentially giving it its name. The magnet has a length of 12.5 m, diameter of 6.3 m and mass of 220 t. Although it was initially designed to sustain a uniform magnetic field of 4 T within the 5.9 m diameter free bore, operation at 3.8 T was chosen in order to increase the lifetime. The magnetic field is returned by a massive iron yoke. The main parameters of the CMS magnet are shown in Table 1.2.

Table 1.2: Parameters of the CMS superconducting solenoid [5] [6].

Field	3.8 T
Inner Bore	5.9 m
Length	12.5 m
Number of Turns	2168
Current	18 160 kA
Stored energy	2.3 GJ

The large bending power of the solenoid is required to bend the tracks of high energy charged particles to an extent where good momentum resolution is achieved. The design requirement for the strength of the magnetic field was the ability to unambiguously determine the sign of the electric charge for muons with a momentum of ≈ 1 TeV/c [5].

The solenoid coil is constructed from four layers of superconducting high-purity niobium-titanium cable co-extruded with pure aluminium, which acts as a thermal stabiliser. The cold mass is cooled down to 4.5 K by liquid helium. If a fast discharge happens (e.g. caused by a magnet quench), about 3 days are necessary to re-cool the coil.

1.2.5 Muon System

The last sub-detector placed on the outermost part of CMS is the muon system. Since the muons are the most penetrating particles detectable by CMS, they have the cleanest signature and play an important role in many physics analyses. Due to their ability to travel through the many layers of the calorimeters, muons are relatively easy to identify and separate from the background.

Figure 1.8: Layout of one quarter of the CMS muon system. Four drift tube (DT, in light orange) stations are labeled MB (muon barrel) and the cathode strip chambers (CSC, in green) are labeled ME (muon endcap). Resistive plate chambers (RPC, in blue) are in both the barrel and the endcaps of CMS, where they are labeled RB and RE, respectively.

The layout of the CMS muon system is shown in Figure 1.8. It consists of the drift tubes (DT), cathode strip chambers (CSC) and resistive plate chambers (RPC). The entire system surrounds the solenoid and covers the pseudorapidity region of $|\eta| < 2.4$.

The drift tubes are located in the barrel region ($|\eta| < 1.2$). Consisting of four stations, they form concentric cylinders around the beam line; there are 250 drift chambers with about 172 000 sensitive wires in total. When a muon passes through the volume, it knocks

electrons off the atoms of the gas, which then follow the electric field and reach the positively-charged wires, providing information on the muon’s position. The chambers are filled with the gas mixture of 85 % Ar and 15 % CO₂, where the muon drift time does not exceed 380 ns. Although this value is bigger than the typical bunch crossing time (25 or 50 ns), it is sufficient because of the small muon rate in this region.

In the endcaps, the cathode strip chambers cover the pseudorapidity region of $0.9 < |\eta| < 2.4$. Each of 468 CSCs is a trapezoidal multi-wire proportional chamber consisting of 6 gas gaps with a plane of radial cathode strips and a plane of anode wires which are roughly perpendicular. A charged muon traversing each plane of a chamber causes gas ionisation and a subsequent electron avalanche which produces a charge on the anode wire and an image charge on the cathode strips. The gas used in CSCs is a mixture of Ar, CO₂ and CF₄.

The resistive plate chambers system is complementary to both DT and CSC systems, and is located in both barrel and endcap regions ($|\eta| < 2.1$). RPCs also operate in avalanche mode with a gas mixture of C₂H₂F₄, C₄H₁₀ and SF₆, and due to an excellent time resolution of about 1 ns they provide fast information for triggering. The spacial resolution is, however, quite limited (≈ 1 cm, compared to ≈ 100 μm for DTs and CSCs).

The muon momentum is measured in both the tracker and the muon system. As it can be seen on Figure 1.9, both sub-systems contribute to the momentum resolution at different p_{T} values. This happens due to the difference in the magnetic field and detector technology. For low- p_{T} muons, the best momentum resolution is obtained in the tracker, whereas in the high- p_{T} region the muon system provides a significant improvement. Therefore, by using information from both the silicon tracker and the muon chambers (i.e. reconstructing the “global muon”), the momentum resolution is improved in the whole p_{T} region up to a ≈ 1 TeV/c level.

1.2.6 Trigger and Data Acquisition

At design LHC luminosity of $L = 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$, approximately 25 collisions are expected to occur at each crossing of the proton bunches. The bunch spacing of 25 ns corresponds to a crossing rate of 40 MHz. Since every event produces ~ 1 MB of raw data, it corresponds to a total data production of 40 TB s^{-1} . Attempting to store all of this data is clearly beyond the available technology. Moreover, only a fraction of events contain hard scattering processes that are of interest, therefore an effective trigger system had to be implemented.

The CMS trigger is a two-level system, consisting of two independent parts: the Level-1 (L1) trigger and the High-Level Trigger (HLT). The L1 trigger is a hardware system implemented in programmable electronics residing partly on detector, and partly in the underground control room located at approximately 90 m from the experimental cavern.

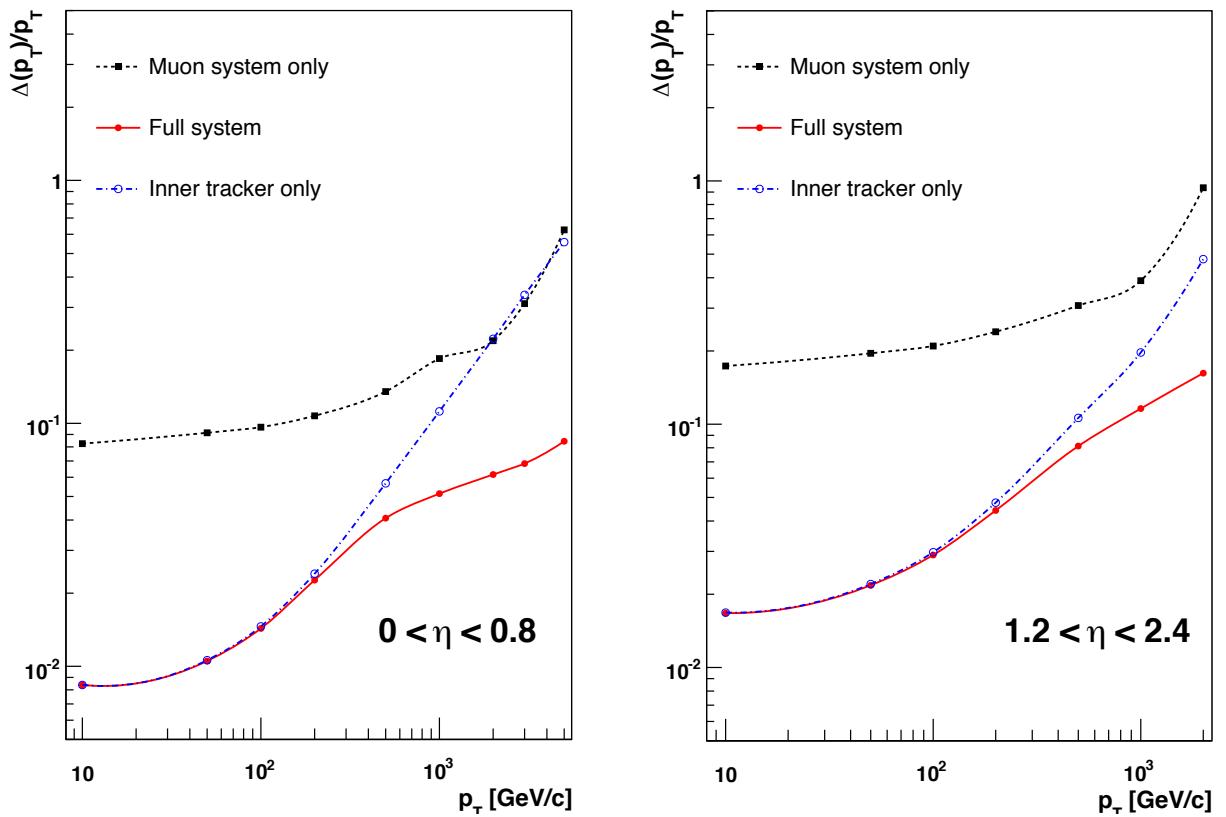

Figure 1.9: The muon transverse momentum resolution as a function of the transverse momentum (p_T) using the muon system only (black), the inner tracking only (blue), and both (red), in regions of $|\eta| < 0.8$ (left) and $1.2 < |\eta| < 2.4$ (right) [3].

The maximum latency between the collision and the L1 accept decision received by front-end electronics is 3.2 μ s. During this amount of time, the complete event information is buffered in pipelined memories on the detector. The only information used for the L1 trigger decision is that from the muon system and the calorimetry. Since the reconstruction of tracks exceeds the time scale required for the L1 decision, the tracker information can't be used. The L1 trigger reduces the event rate from ~ 40 MHz to ~ 100 kHz, corresponding to a data flow of about 100 GB s^{-1} . These events are fed into the HLT system.

The High-Level Trigger is a software system implemented in a single CPU farm, sometimes referred to as the “Event Filter Farm”. Having access to the full event information, customised algorithms of increasing complexity are used which results in a highly flexible trigger system. The event rate is reduced down to ~ 300 Hz, with the final data rate of approximately 300 MB s^{-1} being stored on a large disk cache at the experimental site (the Storage Manager) and later on transferred to CERN Tier 0 for further processing (see Section 1.3).

Since the start of the LHC running, the operating conditions have been changing drastically. During the start-up year of 2010, the instantaneous luminosity went up from about $10^{27} \text{ cm}^{-2} \text{ s}^{-1}$ to approximately $0.2 \times 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$. In 2011 the luminosity ramped up to a factor of 20 above that of 2010, reaching approximately $4 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$. This required a lot of continuous effort to control the trigger rates at reasonable level, whilst also keeping its efficiency acceptable. In 2012 the luminosity was more stable, peaking at $\approx 7.6 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$ which is just a factor of 2 above the 2011 values. However, it still came as a challenge because of the impact of pile-up. At a bunch spacing of 50 ns and increased centre-of-mass energy of 8 TeV, the average number of pile-up vertices nearly doubled comparing to that in 2011, which required a major CPU extension and implementation of sophisticated PU mitigation techniques at the HLT level. The author's contribution to the HLT development of the trigger paths important for top physics is described in Chapter 2.

1.3 Computing

The vast amounts of data delivered by the CMS detector impose high requirements on the offline computing system. During 2010–2012 operation, CMS collected ~ 10 PB of raw data per year. Including Monte Carlo simulations, reconstructed data and analysis skims, the total annual amount of data essentially doubles. To handle the distributed storage and processing of this data, not just for CMS but for the entire high energy physics community using the LHC, a worldwide LHC computing grid (WLCG) has been put in place.

WLCG is a global collaboration of more than 150 computing centres in about 40 countries.

The grid has a tiered architecture, comprising 4 tiers with different resources and services. The first one, Tier 0, is based at CERN and is responsible for data-taking. It accepts raw data from the data acquisition system and repacks it into primary datasets according to the trigger information. The raw data is archived to tape, and is also prompt-reconstructed (within 48 hours) before being distributed to the Tier 1 (T1) centres around the world. There are 8 T1 sites based at large national laboratories in collaborating countries (e.g. RAL in the UK and FNAL in the US). Each of the T1 centres is used for large-scale centrally organised data-processing activities. The data is then distributed in the reduced format (see Section 1.3.1) to a more numerous set of Tier 2 centres, typically located at collaborating universities. Each of these centres is used for the grid-based analysis and Monte Carlo simulation for the whole experiment, as well as local services for groups maintaining them. The last stage of computing system, Tier 3, is meant solely for the local institution's user analysis.

1.3.1 Event Data Model

In the basis of the CMS Event Data Model lies the concept of an event, which is physically a result of a single collision in the LHC. From a software point of view, the event is a C++ object container storing raw data from a single readout of detector electronics (e.g. hits in various sub-detectors), as well as reconstructed data which is based on this information, such as tracks, clusters and physics objects. All these C++ objects are stored in ROOT format [7].

The EDM makes use of three main data formats, based on different levels of detail and precision:

- RAW format, containing full information from the detector as well as L1 and HLT trigger decisions, with the event size of ~ 1.5 MB.
- RECO (reconstructed data) format, which is obtained from raw data by application of pattern recognition and compression algorithms. This data includes reconstructed detector hits, clusters and physics objects (electrons, muons, etc.). The typical event size is ~ 250 kB.
- AOD (Analysis Oriented Data) format, produced by filtering the RECO data from the reconstructed detector objects, leaving just the high-level physics objects required for analysis. The event size is reduced down to ~ 50 kB.

The RECO and AOD data are analysis-ready data formats, produced centrally and used by many physics analysis groups. However, further simplification of the data is also a common

practice. By transforming the C++ objects produced by CMS software into plain basic types or vectors of them, only including the analysis-specific content, the event size can be reduced down to ~ 3 kB level depending on the needs of a particular analysis. This data format is often referred to as private “ntuples”, and it requires specific analysis software capable of restructuring the data into user-defined classes. By following this approach, the analysis can be run locally and generally much faster than processing the RECO or AOD data. However, it requires “ntuplising” this data every time when new centrally-recommended physics objects or corrections are produced.

1.3.2 Analysis Software

Both of the analyses described in this thesis use the CMS software framework¹ (CMSSW), as well as Bristol Analysis Tools² (BAT). The differential cross section analysis also uses an additional level of python scripts for post-processing³.

CMSSW is the key CMS software framework built around the Event Data Model (see Section 1.3.1). The framework is essential for purposes of Monte Carlo simulation, detector calibration and alignment, as well as data reconstruction and analysis. CMSSW has a modular architecture, consisting of one configurable executable (`cmsRun`) and a large set of plug-in modules that contain all the code needed for event processing (reconstruction algorithms, calibration, etc.). Different versions of CMSSW were used for different analyses:

- `CMSSW_4_2_8` for the top mass analysis on 2011 data;
- `CMSSW_4_4_4` for the missing transverse energy analysis on 2011 data;
- `CMSSW_5_3_9` for the top cross pair cross section analysis on 2012 data.

Corresponding versions were used to produce ntuples for processing by BAT, which was used to read the data, apply selections, calculate high-level variables and to create various histograms of distributions. BAT was originally started in 2010 by Dr. Lukasz Kreczko for the needs of the Bristol top group, later on also developed by the author and other researchers from Bristol and affiliated top groups. Like CMSSW, this framework has a modular structure, with its classes falling in four main categories:

- readers, for translating plain data types from ROOT files into C++ objects;

¹<http://cms-sw.github.io/cmssw>

²<https://github.com/BristolTopGroup/AnalysisSoftware>

³<https://github.com/BristolTopGroup/DailyPythonScripts>

- RECO objects, i.e. output of the readers (physical objects like leptons, jets and its collections);
- selections, for application of event selections;
- analysers for creating histograms, applying selections, algorithms, and filling histograms.

All analysers are independent from each other, making the analysis chain stable and reliable. The final set of python scripts is used to prepare the histograms, perform fitting and unfolding procedures (in case of cross section analysis), and producing final tables and plots. Rootpy¹ package was used to access ROOT libraries in python interface, and matplotlib² was used to create plots.

1.4 Object Reconstruction

Most CMS analyses, including the ones described in this thesis, adopt a reconstruction technique called Particle Flow (PF) [8]. This algorithm is used to obtain a global event description at level of individually reconstructed particles by means of combining information coming from all sub-detector systems. The ultimate goal is to determine type, energy and momentum of all the particles in the event with highest possible precision and in the most optimal way. The types of these particles include electrons, muons, charged hadrons, neutral hadrons and photons. All these particles are then used to reconstruct jets (Section 1.4.3), missing transverse energy (Section 1.4.1) and tau leptons from their decay products.

1.4.1 Electron Reconstruction

The reconstruction of the $t\bar{t}$ pair with an electron in the final state imposes high requirements on the electron identification and its energy-momentum measurement, precision of which is of major importance for both top mass and $t\bar{t}$ cross section measurements.

Although the CMS detector is equipped with highly accurate ECAL and tracker systems, electron identification and reconstruction is still a challenging task due to the large amount of tracker material (see Section 1.2.1). This results in a significant Bremsstrahlung photon emission, which often causes an ECAL energy deposit to be widely spread in azimuthal direction because of the high magnetic field. Therefore, dedicated algorithms were developed in order to collect all Bremsstrahlung energy deposits in the calorimeter (Bremsstrahlung recovery), and also to take into account the kinks in the electron trajectory caused by photon emissions.

¹<http://rootpy.org/>

²<http://matplotlib.org/>

Electron reconstruction in CMS has following distinct stages: seeding, track finding, pre-identification, Bremsstrahlung recovery, track-cluster linking and final identification. Historically, the original seeding algorithm was designed and optimised for isolated high- p_T electrons. This approach starts from ECAL clusters, and therefore is called the 'ECAL-driven' seeding. It is based on the property of the ECAL energy deposits to have narrow width in the η coordinate, and to be widely spread in ϕ (azimuthal direction) like it was mentioned above. The electron and all the associated Bremsstrahlung energy deposits form a single "super-cluster", and the ability to correctly determine it affects the overall performance of this method. Only super-clusters with transverse energy above 4 GeV are taken into account. Super-clusters are then matched to pairs or triplets of hits in the inner tracker layers, forming the track seeds on which the electron tracks are built upon.

The performance of the ECAL-driven method is not very well suited for non-isolated and low- p_T electrons. This occurs mainly due to the fact that the super-cluster position and energy can be highly biased by the impact of overlapping particles, especially if the electron happens to be within a jet and therefore non-isolated. Also, high track multiplicity complicates the backward propagation from a super-cluster, because it can be consistent with a number of track seeds corresponding to other particles. To minimise the number of these fake seeds, the ratio between the HCAL and ECAL energy deposits (H/E) is required to be smaller than 0.15. The HCAL towers used in the calculation of this ratio are taken within a cone of $\Delta R = 0.3$ behind the super-cluster position. Although this helps to keep the fake seed rate under control, the efficiency for non-isolated electrons becomes rather limited. As for the low- p_T electrons, the wider azimuthal spread of Bremsstrahlung photons leads to poorer reconstruction of the super-cluster, biasing its position and therefore preventing the efficient matching with a track seed.

Within the particle flow method, efficient reconstruction of non-isolated and low- p_T electrons is particularly important since it affects the reconstruction of jets and missing transverse energy. Therefore, a different ('tracker-driven') seeding algorithm is used, which starts from reconstruction of tracks. The baseline of the CMS track reconstruction is the Kalman filter (KF) [9], which is a linear least-squares estimator based solely on Gaussian probability density functions. It is particularly suitable for muon reconstruction since it is dominated by multiple Coulomb scattering and its impact is well modelled by Gaussian fluctuations. However, this approach usually fails for electrons because Bremsstrahlung photon emission is highly non-Gaussian. To accommodate for the resulting kinks in the electron trajectory, the Gaussian-Sum Filter (GSF) [10] is used, which is essentially a non-linear generalisation of the Kalman Filter. In this method, Bremsstrahlung energy loss is modelled by a Gaussian

mixture, therefore GSF track fit provides a better estimate for the inner and outer track momentum comparing to the KF algorithm. The downside of this approach is its high CPU usage, which means it can be run on a limited number of seeds.

The GSF tracks are reconstructed upon all ECAL-driven seeds. In case of the 'tracker-driven' seeds, a pre-identification based on high-purity KF tracks has been adopted. This procedure starts with the tracks reconstructed with very tight criteria, thus decreasing the fake rate yet compromising on tracking efficiency. Then an iterative-tracking strategy is carried out by means of removing hits unambiguously assigned to tracks from the previous iteration, and also progressively relaxing track seeding criteria. This approach leads to both high efficiency and low fake rate, which is crucial for low- p_T and non-isolated electrons.

In the next step, track-cluster matching has to be performed. In case if electron has negligible Bremsstrahlung emission, the track is well reconstructed with the KF algorithm all the way to the ECAL internal surface, where the closest cluster is matched to the track. The corresponding cluster energy is compared with the track momentum, and if the ratio (E/p) is close to unity, the track is selected. On the contrary, if the electron experiences a significant Bremsstrahlung emission, other track characteristics have to be exploited. In this case a selection based on the number of hits in the tracker and the χ^2_{KF} of the KF fit is applied before running a GSF refit. Finally, the number of hits, the GSF refit χ^2_{GSF} , $\chi^2_{\text{KF}}/\chi^2_{\text{GSF}}$ ratio, the energy loss measured by the track and the quality of the ECAL cluster-track matching are fed into a multivariate analysis using a Boosted Decision Trees (BDT) estimator.

Both tracker-driven and ECAL-driven seeds are used to obtain the GSF track collection of electron candidates. In the particle flow algorithm, it is necessary to link both electron and Bremsstrahlung energy deposits to the GSF track. A super-cluster is linked to a track if the extrapolated position from the outermost tracker measurement is within the boundaries of one of the ECAL cells at the expected depth of the electron shower maximum. The preshower-ECAL and ECAL-HCAL links are made in a similar way.

Another important particle flow procedure, also driven by GSF tracks, is Bremsstrahlung recovery. In order to reconstruct an electron with correctly assigned energy and momentum, it is crucial to identify all energy deposits from Bremsstrahlung photons, thus forming a super-cluster. This procedure is carried out for each tracker layer by computing a straight-line extrapolation tangent to the track, up to the calorimeter. To determine a Bremsstrahlung photon, track-cluster linking is performed as described above. To limit the charged hadron contamination, clusters already assigned to KF tracks are not included in the calculation. Also, the distance in η coordinate between the extrapolation and the cluster is required to be smaller than 0.015, which helps to reduce the neutral particles background.

1.4.1.1 Electron Identification

Electron reconstruction in CMS is based on a characteristic signature that electrons leave in the tracker and calorimetry systems. However, other objects like charged hadrons, jets or photon conversions can produce very similar signatures and therefore may be reconstructed as electrons. Therefore, in order to distinguish these “fake” electrons from “real” ones, a further selection has to be applied. This procedure is referred to as electron identification (or electron ID).

Initially the electron identification is performed at the final stage of the electron reconstruction process. The working points of the cuts applied are selected to be loose enough in order to satisfy most CMS analyses requirements. Afterwards, more specific (tighter) ID cuts are applied for each individual analysis, defining the working point in the trade-off between selection efficiency and fakes contamination. This will be discussed separately in the selection description for each analysis in corresponding chapters.

There are several electron identification algorithms used by various CMS analyses, and four of them are used in the analyses described in this thesis: simple cut-based (SCB ID), cuts in categories (CiC ID), particle flow (PF ID) and multi-variate analysis (MVA ID).

Simple cut-based identification is used in the High-Level Trigger, and therefore has to be as simple, fast and robust as possible. Cuts are applied on the following variables:

- H/E , i.e. the ratio of hadronic energy of the HCAL towers centred at the super-cluster position of the electron in a cone of radius $\Delta R = 0.15$, and the super-cluster electromagnetic energy;
- $\Delta\eta_{\text{in}}$, i.e. the difference in η between the extrapolated track position and η of the super-cluster;
- $\Delta\phi_{\text{in}}$, i.e. the difference in ϕ between the extrapolated track position and ϕ of the super-cluster;
- $\sigma_{i\eta,i\eta}$, i.e. cluster shape of the electron energy in a 5×5 block of crystals around the seed crystal (the one with the highest energy) [11]:

$$\sigma_{i\eta,i\eta} = \sum_{5 \times 5 \text{ crystals}} (\eta_i - \eta_{\text{seed cluster}})^2 \frac{E_i}{E_{\text{seed cluster}}} \quad (1.5)$$

Although this identification method has an advantage of its simplicity, it does not show the best signal efficiency and background rejection. One of the more complex methods is

the CiC ID, which exploits the categorisation of electrons. It is optimised to select electrons from different sources (W , Z and J/ψ decays) and reject fakes from jets or conversions. In order to achieve higher efficiency, electron candidates are split into categories with different signal to background ratio, allowing to better tune the working points of the cuts. The first step in categorisation is done by division between barrel and endcap regions of the detector. Since the properties of both the tracker and calorimetry systems differ significantly in these two regions, different cuts are applied. The second step is based on the following observables:

- f_{brem} , or measured bremsstrahlung fraction, defined as:

$$f_{\text{brem}} = \frac{p_{\text{in}} - p_{\text{out}}}{p_{\text{in}}} \quad (1.6)$$

where p_{in} is the initial track momentum at the vertex and p_{out} is the track momentum at the last hit;

- E/p , which is the ratio of the super-cluster energy and the initial track momentum.

Three categories of electron candidates are distinguished [12]:

- “Low-Brem”: $0.9 < E/p < 1.2 - f_{\text{brem}} < 0.12$ (barrel), $0.82 < E/p < 1.22 - f_{\text{brem}} < 0.2$ (endcap), the fake-like region with high number of both real and fake electrons;
- “Bremming”: $0.9 < E/p < 1.2 - f_{\text{brem}} > 0.12$ (barrel), $0.82 < E/p < 1.22 - f_{\text{brem}} > 0.2$ (endcap), the electrons-like region with a little contamination from fakes;
- “Bad-Track”: remaining regions with a low number of real electrons.

The third and the final step in categorisation is based simply on the electron transverse energy, with the lower threshold taken as 10 GeV. In each category, the selection is performed on the basic ID variables already mentioned above for the simple cut-based identification. On top of these variables, isolation and conversion rejection variables are also used, they are discussed in Section 1.4.1.2 and Section 1.4.1.3, respectively.

The cuts within CiC ID are applied in order to maximise the signal to background ratio. Depending on the needs of different analyses, nine levels of cut severity are implemented: *VeryLoose*, *Loose*, *Medium*, *Tight*, *SuperTight*, *HyperTight(1-4)*. Each step decreases the fake rate by about a factor of two for electrons with $E_T > 20$ GeV [12]. The CiC ID is used as a primary electron identification method in the Top Mass analysis (Chapter 3).

Particle flow ID is the final step of the particle flow electron reconstruction. Following the particle flow concept, it uses information from all the CMS sub-detectors obtained in previous

reconstruction steps to build new observables for electron identification. The complete list of PF ID observables is given below:

- p_T and η of the GSF track;
- GSF σ_{p_T}/p_T , transverse momentum resolution of the GSF track;
- $\# \text{hits}_{\text{KF}}$, number of reconstructed KF track hits;
- χ^2_{GSF} and χ^2_{KF} , GSF and KF goodness-of-fits;
- $\Delta\eta$: distance in η between the position of the cluster and the extrapolated position of the GSF track;
- $\sigma_{\eta\eta}$, cluster shape (Equation 1.5) of the ECAL cluster linked to the GSF track;
- $H/(H+E_e)$, hadron fraction of the shower, where H is the energy of the hadron cluster linked to the GSF track;
- $(E_e + \sum E_\gamma)/p_{\text{in}}$, ratio between the super-cluster energy and the inner track momentum;
- E_e/p_{out} , ratio between the electron cluster energy and the track outer-momentum;
- $\sum E_\gamma/(p_{\text{in}} - p_{\text{out}})$, the ratio between the Bremsstrahlung photon energy as measured by ECAL and by the tracker;
- *EarlyBrem*, flag of $(E_e + \sum E_\gamma) > p_{\text{in}}$ inequality, corresponding to an electron emitting an “early” Bremsstrahlung photon, i.e. before it has crossed at least three tracker layers;
- *LateBrem*, flag of $E_e > p_{\text{out}}$ inequality, corresponding to an electron emitting a “late” Bremsstrahlung electron, when the ECAL clustering is not able to disentangle the overlapping electron and photon showers;
- $f_{\text{brem}} = (p_{\text{in}} - p_{\text{out}})/p_{\text{in}}$, Bremsstrahlung fraction (Equation 1.6).

All these variables are combined into a single discriminator by a multivariate analysis technique (BDT method), which has been trained on signal and background Monte Carlo samples. PF ID is a relatively loose identification method, since it has to satisfy the needs of all analyses using particle flow collections.

Finally, MVA electron identification is used in top cross sections analysis on 2012 data. It is another multivariate analysis technique, optimised to select isolated electrons from W and Z decays. The variables used in MVA ID are also combined into a single discriminator, they are largely similar to the ones used in PF ID:

- p_T and η of the GSF track;
- $\#\text{hits}_{\text{KF}}$, number of reconstructed KF track hits;
- χ^2_{GSF} and χ^2_{KF} , GSF and KF goodness-of-fits;
- $\Delta\eta$: distance in η between the position of the cluster and the extrapolated position of the GSF track;
- $\Delta\phi$: distance in ϕ between the position of the cluster and the extrapolated position of the track;
- $\Delta\eta_{vtx}$: distance in η between the position of the cluster and the position of the GSF track at vertex;
- $\Delta\phi_{vtx}$: distance in ϕ between the position of the cluster and the position of the GSF track at vertex;
- $\sigma_{\eta\eta}$, cluster shape in η ;
- $\sigma_{\phi\phi}$, cluster shape in ϕ ;
- η width of the super-cluster;
- ϕ width of the super-cluster;
- H/E , ratio of HCAL and ECAL cluster energy;
- $E_{\text{super-cluster}}/p_T$, ratio between the super-cluster energy and the track momentum;
- $1/E_{\text{super-cluster}} - 1/p_T$, difference between inverse super-cluster energy and inverse track momentum;
- E_e/p_{out} , ratio between the electron cluster energy and the track outer-momentum;
- $1 - E_{1\times 5}/E_{5\times 5}$, where $E_{1\times 5}$ is the energy in the central 1×5 strip of the 5×5 electron cluster and $E_{5\times 5}$ its total energy;
- $E_{3\times 3}/E_{\text{super-cluster, raw}}$, ratio of the energy of a cluster of 3×3 and the uncorrected (raw) energy of the super-cluster;
- $E_{\text{PS}}/E_{\text{super-cluster, raw}}$, ratio of the energy in the preshower detector and the raw super-cluster energy (only in the endcap region).

1.4.1.2 Electron Isolation

Isolation is an observable that allows to distinguish prompt electrons (i.e. the ones from W and Z decays) from jets faking electrons and electrons within jets. It is essentially a measure of activity around the particle. In CMS, there are two different ways of quantifying isolation: detector-based and particle-based. The detector-based isolation is defined separately for each detector sub-system (tracker, ECAL and HCAL):

- Tracker isolation, calculated as the sum of transverse momenta of all track within a cone of $\Delta R = 0.3$ around the electron, excluding the electron momentum itself;
- ECAL isolation, i.e. the sum of transverse energy of all ECAL clusters within a cone of $\Delta R = 0.3$ around the super-cluster position. The footprint of the original electron is also removed;
- HCAL isolation, defined as the sum of transverse energy of all HCAL towers within a cone of $\Delta R = 0.3$ centred at the super-cluster position.

Particle-based isolation exploits the particle flow information: it is calculated as the sum of transverse energy of all PF particles in the cone of $\Delta R = 0.3$ around the electron. Both detector-based and particle-based isolation definitions are often normalised to the electron transverse momentum (or energy in case of calorimeter isolation) in order to improve signal efficiency. The normalised sum of the tracker, ECAL and HCAL isolation variables is referred to as detector-based relative isolation (or RellIso), similarly normalised particle-based isolation is called PF RellIso. These quantities are crucial in various methods to estimate the QCD background contribution for many analyses, and will be used for both electrons and muons throughout this thesis.

1.4.1.3 Identification of photon conversions

Interacting with detector material, photons can convert into electron-positron pairs. Due to the large amount of material budget in the tracker (Figure 1.4), especially in the endcap region, there is a high chance of conversions to happen. The resulting electrons can successfully fake prompt signal electrons, passing all the identification criteria and appearing isolated if the initial photon was isolated, too. Therefore conversions constitute a large proportion of the QCD background to top signal. The electron-positron pair may not be symmetrical in transverse momenta, therefore a veto on a second electron is not sufficient to reject such electrons and other conversion identification criteria are necessary.

The simplest method is based on counting the number of missing hits in the tracker. Conversions are most likely to happen at some distance from the interaction point, essentially

anywhere between the point of photon production and the end of the tracker. Therefore electrons produced in such conversions are likely not to traverse through all the pixel layers. To separate these electrons from the prompt ones, a cut on the number of missing layers can be used. However, this approach fails if conversion occurs in the beam pipe, or if the reconstructed electron track is paired with unrelated hits in the tracker, making it look like a prompt electron.

A slightly more sophisticated method is a partner track method. It is based on geometrical cuts on $dist$ and $dcot$ variables, which refer to the distances between tangent points of any two tracks in the $r - \phi$ -plane and $r - z$ -plane, respectively:

$$dist = ||\vec{r}_1 - \vec{r}_2| - r_1 - r_2| \quad (1.7)$$

$$dcot = \left| \frac{1}{\tan \theta_1} - \frac{1}{\tan \theta_2} \right| \quad (1.8)$$

Here $\vec{r}_{1,2}$ are radial vectors of the two tracks, $r_{1,2}$ are the track radii and $\theta_{1,2}$ – angles between the tracks and the beam pipe. Apart from the cuts on $dist$ and $dcot$ variables, tracks should have opposite charge in order to be considered to come from a photon conversion.

These two methods for conversion identification were used in the top mass analysis on 2011 data. For the top cross sections analysis on 2012 data, along with the number of hits method, a more advanced technique called vertex fit was used. It is essentially a full vertex fit of all pairs of tracks, with the selection being made on the fit probability. The method benefits from the full use of track uncertainties and covariances, combining all information into a single discriminator. However, increased complexity of this technique makes it more CPU-intensive than the partner track method.

1.4.2 Muon Reconstruction

A good muon reconstruction and identification was one of the main CMS design requirements. Initially, muons are reconstructed independently in the tracker (“tracker tracks”) and in the muon system (“standalone muon tracks”) using the Kalman Filter technique [9]. Based on these objects, two different reconstruction methods are used: [13]

- Global muon reconstruction. Each standalone muon track reconstructed in the muon system is matched with the tracker track by propagating onto a common surface. A global fit is performed on the combined collection of hits from both tracks, and the resulting muon is referred to as a *global muon*.
- Tracker muon reconstruction. All tracker tracks above certain threshold ($p_T > 0.5$ GeV,

$p > 0.5$ GeV) are extrapolated to the muon system, taking into account possible energy losses, magnetic field and multiple Coulomb scattering. If the track matches at least one muon segment in the muon system, i.e. a short track stub made of DT or CSC hits, it is considered a *tracker muon*.

Global muon reconstruction has a high efficiency for high- p_T muons, penetrating through more than one muon station. On the contrary, tracker muon reconstruction is more efficient for low- p_T muons ($p_T < 5$ GeV), as it requires just a single muon segment. Since the $t\bar{t}$ analyses described in this thesis have a semileptonic signature with exactly one energetic muon in the final state (in case of the muon channel), only the global muon reconstruction method is used, as its momentum resolution at high transverse momenta benefits from both the tracker and the muon system (Figure 1.9).

Following the reconstruction, the quality of the muon objects is verified by applying identification criteria. This is done in order to suppress hadronic punch-through, muons from decays in flight and cosmic muons. Selection is applied on the following observables:

- normalised χ^2 ($\chi^2/\text{number of degrees of freedom}$) of the global muon fit;
- number of muon chamber hits in the global muon fit;
- number of muon stations with muon segments;
- transverse impact parameter d_{xy} (closest approach of the track to the primary vertex);
- longitudinal distance d_z of the tracker track w.r.t. the primary vertex;
- number of hits in the pixel detector;
- number of hits in the tracker layers.

The muon identification also exploits the CMS particle flow event reconstruction, making use of information coming from all sub-detectors. Particle flow muons (PF muons) are identified by imposing selection on all muon candidates reconstructed with the global muon method. This selection was optimised for identification of muons in jets, minimising the fake rate from misidentified charged hadrons, which is crucial for correct reconstruction of jets and missing transverse energy (described in more detail in the following sections). Depending on the analysis specifics, isolation requirements can also be applied; isolation definitions closely follow the ones for electrons (Section 1.4.1.2).

1.4.3 Jet Reconstruction

Hadronisation of quarks and gluons leads to production of narrow cones of particles moving in approximately one direction, called jets. This happens due to colour confinement, as particles carrying a colour charge cannot exist in free form, they have to fragment into hadrons before they can be detected directly. Therefore, to measure the initial parton's momentum and energy, all these particles must be combined into jets.

The CMS particle flow algorithm implies reconstruction of individual particles (charged and neutral hadrons, electrons, muons, photons) before combining (or clustering) them into jets. A few different jet clustering techniques exist, but the one used predominantly in CMS and exclusively in this work is anti- k_t algorithm [14], which defines the distance between constituent particles as:

$$d_{ij} = \min \left(\frac{1}{k_{t,i}^2}, \frac{1}{k_{t,j}^2} \right) \frac{\Delta_{i,j}^2}{R^2} \quad (1.9)$$

where $\Delta_{i,j}^2 = (y_i - y_j)^2 + (\phi_i - \phi_j)^2$, $k_{t,i/j}$, $y_{i/j}$ and $\phi_{i/j}$ are respectively transverse momenta, rapidities and azimuth angles of particles i/j , and R is the radius parameter.

The clustering proceeds by identifying the smallest distances between particles and recombining them until all jets are formed and no particles are left. An event typically has a few well-separated hard (high- p_T) particles and a large amount of soft (low- p_T) particles. The distance d_{1i} between a hard particle 1 and a soft particle i will be fully determined by the transverse momentum of the hard particle and the Δ_{1i} separation. On the other hand, distance between soft particles with similar separation will be substantially larger. Therefore, soft particles tend to cluster around the hard ones before they cluster amongst themselves. On the output, the anti- k_t algorithm forms conical jets with boundaries resilient to soft radiation.

1.4.3.1 Jet Energy Corrections

Due to non-linear and non-uniform response of the calorimetry systems, jets reconstructed using detector inputs typically have energies different to the ones of corresponding Monte Carlo particle jets (or generator jets), reconstructed by clustering the four-momenta of all stable particles generated in Monte Carlo simulation. Therefore some mapping procedure is necessary. Corrections applied to reconstructed jets in order to translate the measured energy to the true particle (or parton) energy are referred to as jet energy corrections, or JEC.

CMS has adopted a factorised approach of applying jet energy corrections, meaning that each correction level takes care of a different effect. The set of corrections is applied sequentially, i.e. the output of each step is the input to the next one. Essentially, each level

of correction is a scaling of a jet four-momentum, with a scale factor depending on various parameters of the jet, typically pseudorapidity and transverse momentum. Currently, the correction levels go as follows:

- L1 Offset correction;
- L2 Relative (η) correction;
- L3 Absolute (p_T) correction;
- L4 EMF (electromagnetic energy fraction) correction;
- L5 Flavour correction;
- L6 UE (underlying event) correction;
- L7 Parton correction.

The goal of the L1 correction is subtraction of pile-up and electronic noise contributions from the jet energy. The energy from pile-up vertices can be deposited in calorimeters since the additional proton-proton collisions occur close enough in time to the hard scattering process. Electronic noise in calorimeter readouts also creates additional energy offset which needs to be corrected for. The scale factors for L1 correction are derived using data-driven methods (zero-bias collisions).

The relative L2 correction is designed to flatten the jet response in pseudorapidity. These corrections are extracted with respect to the barrel region in bins of p_T , and therefore are uncorrelated with the following L3 corrections. Both Monte Carlo and data-driven (dijet balance) methods are used to derive the L2 scale factors. Once a jet is corrected for η dependence, it is corrected back to the particle level by applying absolute L3 correction. The goal of this correction is to flatten the jet response in transverse momentum. Derivation of L3 scale factors is done by using Monte Carlo truth information, or data-driven Z/γ +jet balance techniques.

The L4 EMF correction takes care of variations in jet response with respect to electromagnetic energy fraction, i.e. the fraction of energy deposited in ECAL by hadrons. Although it has been shown that EMF-dependent correction in three parameters (p_T , η , EMF) can improve the observed jet resolution, this correction is optional for most CMS analyses and hasn't been used in this work.

Another optional correction is the L5 flavour correction, which is intended to correct the jets depending on the flavour of initiating partons, i.e. light quarks, heavy (b and c quarks),

or gluons. Jets originating from heavy quarks are different from light quark jets in a few aspects. The average number of charged hadrons within b -jets is higher than the one for the light jets, although the average momentum of charge hadrons is smaller. Moreover, b -hadrons have a larger branching fraction into semileptonic decays with neutrinos in the final state that cannot be detected. All these factors may lead to a substantially smaller charged hadron energy fraction comparing to the light jets, therefore the average calorimeter energy response is lower for the b -jets. These effects are meant to be taken care of by the L5 correction, which is derived either from Monte Carlo or data-driven $t\bar{t}$ events.

Underlying event [15] refers to all the activity in the proton-proton collision apart from the process of interest, i.e. the hard scattering process. It includes particles coming from additional parton interactions (or multiple scatterings) and beam remnants. Depending on the analysis goals, underlying event may also include initial and final state radiation (ISR and FSR) which represent the soft gluon radiation before and after the hard scattering process, respectively. Underlying event activity results in production of additional soft jets which can bias the jet energy measurement. Optional L6 UE correction attempts to mitigate such bias. However, it was not used in the analyses described in this thesis, since underlying event is an intrinsic part of proton-proton interactions effectively modelled by Monte Carlo simulation. In particular, the top cross sections analysis is designed to be very sensitive to such higher-order processes, and not taking them into account may result in compromising the discriminating power between Monte Carlo generators.

Finally, L7 parton correction attempts to correct the jet energies back to the parton level. It is also optional and was only used in the top mass analysis. The correction factors were derived from Monte Carlo simulations by comparing the generator jets momenta to their matched partons.

Due to the fact that CMS simulation is not perfectly tuned to the data yet, additional residual L2L3 corrections are applied in order to achieve better agreement between data and simulation. It is essentially a small residual η - and p_T -dependent calibration applied exclusively to data, which will remain in place until CMS develops a perfectly tuned simulation reproducing the data features out of the box.

1.4.3.2 Particle Flow Jet Identification

To ensure the quality of the jets, a final identification criteria are applied to all jet objects. Particle flow jet identification (or PF jet ID) is used to reduce the noise and rate of electrons reconstructed as jets. The cuts are applied on the following observables :

- number of constituent particles;

- NHF (neutral hadron energy fraction);
- CHF (charged hadron energy fraction);
- NEF (neutral electromagnetic energy fraction);
- CEF (charged electromagnetic energy fraction).

A rather loose identification cuts (referred to as “loose PF jet ID”) were used in this work: a requirement of more than one constituent particle in the jet, $\text{NHF} < 0.99$, $\text{CHF} < 0.99$, $\text{NEF} > 0$ and $\text{CEF} > 0$ in pseudorapidity region of $\eta < 2.4$.

1.4.3.3 b-tagging

The identification of jets originating from b-quarks, or b-tagging, is one of the most important tools in top quark physics, capable of significantly decreasing the background contamination of signal processes. A variety of b-tagging algorithms have been developed by CMS [16], and the one that was used in this work is called combined secondary vertex (CSV) algorithm. It is based on the fact that b-hadrons have a significant lifetime ($\sim 10^{-12}$ s) and can travel a distance of a few centimetres before decaying. Therefore jets originating from b-quarks are likely to have a secondary vertex located at a considerable distance from the primary vertex, which can be used as an efficient discriminator between light jets and b-jets. In order to maximise its efficiency, apart from the secondary vertex information the CSV algorithm also exploits the track-based lifetime information. The following variables are used in the algorithm:

- number of tracks in the jet;
- number of tracks at the secondary vertex;
- secondary vertex category;
- secondary vertex invariant mass;
- ratio of the total track energy at secondary vertex with respect to all tracks in the jet;
- pseudorapidities of tracks at secondary vertex with respect to the jet axis;
- impact parameter significance (i.e. ratio of IP to its uncertainty) of the first track that increases the invariant mass above the charm threshold of 1.5 GeV (tracks are ordered by IP significance; the mass of the system is recalculated after adding each track);

- impact parameter significances of each track in the jet.

All these observables are combined into a single discriminator, the “medium” working point of which is used in this work. It provides $\sim 70\%$ b-tagging efficiency for mis-tag rate of approximately 1 % [16].

1.4.4 Missing Transverse Energy

Due to the energy and momentum conservation, the sum of transverse momenta and energy of all particles in the final state of proton-proton collisions is expected to be zero. However, some particles can escape the detector without being reconstructed, therefore creating the imbalance in transverse momentum which is referred to as missing transverse energy, defined as:

$$\vec{E}_T^{\text{miss}} = - \sum_i \vec{p}_T^i \quad (1.10)$$

where \vec{p}_T^i are the transverse momentum vectors of all reconstructed particles. The modulus of \vec{E}_T^{miss} vector is denoted by E_T^{miss} .

Accurate reconstruction of missing transverse energy is crucial for precise measurements of Standard Model processes with neutrinos in the final state. Top quark pair semileptonic decay is one of such processes, therefore analyses covered in this thesis implicitly (top mass) or explicitly ($t\bar{t}$ cross section with respect to E_T^{miss} -related variables) rely on efficient reconstruction of E_T^{miss} . Misidentification and misreconstruction of any visible particles in the event contribute to E_T^{miss} measurement, therefore it is a rather demanding task.

Just like in the case of leptons and jets, particle flow was used for E_T^{miss} reconstruction: in equation 1.10 the transverse momentum vectors are of the particles reconstructed using particle flow algorithm. This procedure gives so-called raw E_T^{miss} on the output. The raw E_T^{miss} is systematically different from true E_T^{miss} , which denotes the transverse momentum carried by invisible particles. This happens mainly due to non-compensating nature of the calorimeters, effects of pile-up, noise, etc. Therefore, a set of corrections is applied:

- Type-0, which corrects E_T^{miss} for pile-up;
- Type-I, a propagation of jet energy corrections (Section 1.4.3.1) to E_T^{miss} ;
- xy -shift correction, reducing the E_T^{miss} ϕ modulation.

The causes of systematic E_T^{miss} ϕ modulation include detector misalignment, beam spot displacement, inactive calorimeter cells and anisotropic detector response. xy -shift correction mitigates these effects, making the measured E_T^{miss} distribution closer to true E_T^{miss} distribution which is flat in ϕ because of the rotational symmetry of the collisions.

All these corrections were applied to missing transverse energy in the analyses described in this work. However, the xy -shift correction was not applied in the top mass analysis, since it was not available at the time. As this analysis is not particularly sensitive to E_T^{miss} , the ϕ modulation is not expected to affect the top mass measurement and its resolution.

1.5 Summary

In this chapter, the Large Hadron Collider (LHC) has been introduced to the reader. The CMS experiment including all its subsystems has been described in detail, the overview of the CMS computing model and analysis software have been shown. Reconstruction and identification methods of various analysis objects including particle flow algorithm have been discussed in detail.

2. High level triggers for Top Physics

The LHC is often referred to as a top quark factory, producing a $t\bar{t}$ pair nearly each second of its nominal operation. While the production rate of ≈ 1 Hz seems manageable in terms of recording the data, it is significantly complicated by background processes with similar signatures occurring at much higher rates.

The trigger is the starting point of any physics event selection process, and therefore is clearly important for any physics analysis. As it was mentioned in Section 1.2.6, the CMS L1 trigger rate is limited to ~ 100 kHz. In order to meet the data recording constraints of approximately 300 MB s^{-1} , this rate is further reduced down to ~ 300 Hz, which is done by the HLT system. The total rate budget has to be shared between various physics analysis groups (e.g. Top, Higgs, Exotica, etc). Corresponding allocations are determined by CMS trigger coordination according to CMS physics goals, and can be a matter of serious debate.

During the LHC operation in 2011 and 2012 under conditions of gradual increase of instantaneous luminosity and pile-up, but very limited rate budget, trigger developers constantly tackled the challenge of finding the best compromise between growing rates and maintaining reasonable signal acceptance. While the simplest approach is tightening the cuts on physical quantities like lepton or jet transverse momenta, it is not favourable since it lowers the number of stored signal events and decreases the phase space which is crucial for new physics searches as well as Standard Model precision measurements. Therefore, development of more efficient algorithms allowing to keep high level of acceptance for signal events, whilst effectively rejecting background events, is the most preferable solution. This can often be achieved by increasing the level of approximation of the online (HLT) object reconstruction, making the algorithms closer to their sophisticated offline counterparts. However, it leads to a higher execution time, which is limited by computing resources available for HLT reconstruction. Hence, the CPU timing is another major constraint faced by the HLT developers.

This chapter covers the author’s contribution to development and verification of High-Level Triggers for top physics with semileptonic signature, where one of the W bosons decays into an electron and a neutrino. The description of top triggers, efficiency measurement, validation of jet energy corrections and pile-up subtraction applied at the HLT level are discussed in relevant sections of this chapter.

2.1 Level-1 triggers

The CMS L1 trigger [17] is built of custom electronics processing the data from the calorimeters and the muon system. It is the first filtering stage of any physics selection, therefore it has high requirements on efficiency and phase space. The input rate of events, i.e. the beam crossing frequency of $\sim 5 \times 10^8$ Hz must be reduced down to ~ 100 kHz, being a major challenge considering a gradual increase of instantaneous luminosity throughout the LHC operation. The rate budget of ~ 100 kHz is shared between several L1 triggers corresponding to different physics objects being present in the event. For top physics signatures with a single electron in the final state, the following triggers have been used:

- L1_SingleEG_18
- L1_SingleEG_20
- L1_SingleEG_22

These triggers are referred to as electron/photon (e/γ , or EG) triggers. They scan the ECAL for groups of crystal cells (4×4) with a cumulative energy above the threshold that is suggested by the name of the trigger (18 GeV, 20 GeV and 22 GeV). The choice of threshold is determined by sustainability of the trigger rate at a given instantaneous luminosity.

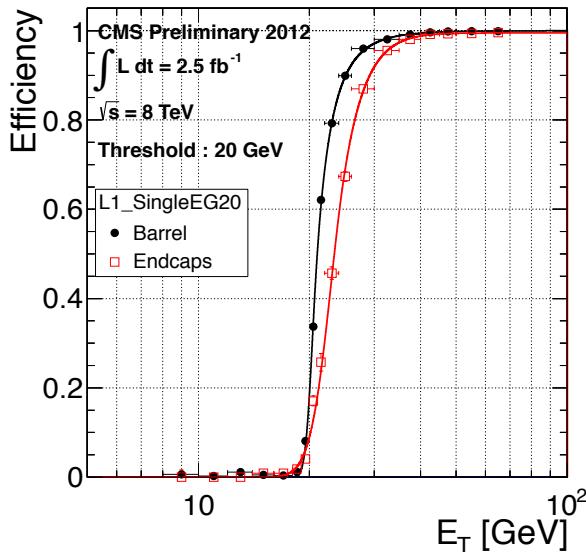

Figure 2.1: Efficiency of the 20 GeV e/γ trigger as a function of offline E_T , shown separately for barrel and endcap regions [18].

The efficiency of the L1_SingleEG_20 trigger as a function of the offline-reconstructed electron transverse momentum is shown on Figure 2.1. The L1 trigger decisions are then used as an input “seeds” to the HLT system, which is described in the following section.

2.2 High-level triggers for top physics

The High-Level Trigger [19] is the crucial part of CMS event selection process. As it was mentioned in Section 1.2.6, it is based on software algorithms running on the Event Filter Farm, i.e. a large cluster of commercial CPUs. The HLT reconstruction, often referred to as online reconstruction, is implemented in the same software framework (CMSSW) which is used for offline reconstruction, and the algorithms can be very similar. However, the key difference between online and offline reconstruction is the running time. Since the HLT selection has to be performed in real time, it imposes a significant constraint on computing resources, enforcing to compromise on robustness and efficiency of online algorithms. With an exception of small samples for performance monitoring, data rejected by the HLT is lost irrevocably. Therefore, correct and efficient operation of the HLT is of major importance for CMS physics programme.

Modular structure of CMSSW provides high flexibility in use of selection and reconstruction algorithms, allowing their continuous optimisation according to changes in physics needs and data-taking conditions. Various modules account for reconstruction of different physics objects and their matching with L1 objects, filtering, logging, monitoring, etc. All these modules are grouped into so-called trigger “paths”, ultimately giving trigger decisions on whether to accept an event or not. A typical example of a trigger path used for top physics is an electron-plus-jets trigger, which requires the presence of isolated electron and at least three energetic jets in the event.

There are two types of trigger paths: prescaled and unprescaled. Prescaling is a method of reducing the trigger rate by only recording a fraction of events that pass the trigger selection. For example, if the prescale value of a particular trigger is 10, only one out of ten events that fire the trigger will be actually recorded. Usually prescaled triggers are used for performance monitoring and background estimation as they can impose a much looser selection criteria yet still have manageable rate. However, such triggers are unfavourable for signal selection, as they greatly reduce signal acceptance.

A set of trigger paths and their prescale factors is combined in the HLT configuration, referred to as the HLT menu or table [20]. Since the start of data-taking in 2010, the CMS trigger coordination adopted a “trigger train” model, implying the schedule of regular deadlines for updates in the trigger menu. These deadlines are usually imposed fortnightly,

according to changes in instantaneous luminosity or other alterations in data-taking conditions. In order for a trigger path to be included in the trigger menu, it has to be implemented in the HLT configurations database, validated by measuring the trigger rate and signal efficiency, tested for CPU timing and finally approved by the trigger studies group.

As it was mentioned before, the top quark pair decay covered in this work has a semileptonic signature, containing an electron, at least four jets and a neutrino in form of E_T^{miss} . Due to the nature of the decay, all these objects are highly energetic and can be triggered on with rather high thresholds on transverse energy. During the start-up year of 2010 when the instantaneous luminosity went up from $\sim 10^{27} \text{ cm}^{-2} \text{ s}^{-1}$ to $\sim 10^{31} \text{ cm}^{-2} \text{ s}^{-1}$, top analyses with the signature of interest used the single electron trigger, requiring just one electron with certain isolation and transverse momentum criteria. However, by extrapolating the trigger rates on higher luminosities foreseen in the following years it became obvious that the single electron trigger rate would quickly become too high for the rate budget restrictions at the time. Therefore, alternative ways of adding other objects from the $t\bar{t}$ signature were explored, naturally leading to electron-plus-jets trigger solution.

A typical electron-plus-jets trigger consists of a standard electron module, a jet module, a cleaning module to remove overlap between jet and electron collections, and a jet multiplicity filter. The electron module is constructed from the following sub-modules:

- L1 object and ECAL super-cluster matching;
- ECAL transverse energy filter;
- ECAL electron ID and isolation filter;
- HCAL electron ID and isolation filter;
- tracker electron ID and isolation filter.

To minimise the total running time, all the sub-modules are ordered by speed, starting from the fastest. The matching module finds the ECAL super-cluster closest to the L1 object in η and ϕ dimensions. If the super-cluster is located within a certain η and ϕ range, the event is passed to the next module, otherwise it is rejected.

The following (ECAL) module calculates the super-cluster transverse energy (E_T), and in case if it is above 25 GeV, the electron ID and isolation criteria are imposed for both ECAL and HCAL (see Section 1.4.1). The working points of identification and isolation and their naming conventions are shown in Table 2.1.

In the main trigger path used for signal rather than background estimation, Very Tight (VT) working point for calorimeter identification (CaloID) and Tight (T) working point for calorimeter isolation (CaloIso) were used. This was motivated by consistency with similar criteria for the single electron trigger used in 2010.

For the events that pass all described criteria in the electron module, a simplified algorithm for offline iterative tracking is applied. This algorithm has a faster running time at the expense of worse resolution. In order to decrease the CPU usage, the Combinatorial Track Finder (CTF) [21] is used instead of the GSF one, and the tracking is confined to a small region around the electron. The events are required to pass the tight criteria of the tracker electron ID (TrkId) which is calculated at this stage. Finally, the tight working point of the tracker isolation (TrkIso) is applied, where the track p_T is summed over all tracks within $\Delta R = 0.3$ cone around the electron track, excluding the electron itself. Provided that event passes all the electron sub-modules, the jet module is then executed.

The jet reconstruction is performed with the anti- k_t algorithm (see Section 1.4.3) with a radius parameter of $R = 0.5$. Historically, at the early stages of LHC operation, CMS analyses mostly used calorimeter jets, i.e. jets reconstructed using calorimeter information exclusively. Therefore, initially the trigger jet module used calorimeter jet collection, which provided fast reconstruction yet worse resolution hence lower trigger efficiency comparing to PF jets which were introduced later on during 2011 data-taking. In order to work online, PF jet reconstruction was modified to be compatible with the simplified tracking algorithm. Despite the fact that running the jet module with PF jet reconstruction is highly CPU-intensive and therefore can not be used as an unprescaled stand-alone trigger, it works effectively together with the electron module since it reduces the input event rate considerably. Both calorimeter and PF jet versions of the module impose the 30 GeV cut on transverse momentum on the jets as well as the pseudorapidity cut of $|\eta| < 2.6$. Subsequently, the jet

Working point	CaloID	CaloIso	TrkId	TrkIso
VeryLoose (VL)	$H/E < 0.15$ (0.10) $\sigma_{inj} < 0.024$ (0.040)	ECAL iso/ $E_T < 0.2$ (0.2) HCAL iso/ $E_T < 0.2$ (0.2)	$\Delta\eta < 0.01$ (0.01) $\Delta\phi < 0.15$ (0.10)	track iso/ $p_T < 0.2$ (0.2)
Loose (L)	$H/E < 0.15$ (0.10) $\sigma_{inj} < 0.014$ (0.035)			
Tight (T)	$H/E < 0.10$ (0.075) $\sigma_{inj} < 0.011$ (0.031)	ECAL iso/ $E_T < 0.125$ (0.075) HCAL iso/ $E_T < 0.125$ (0.125)	$\Delta\eta < 0.008$ (0.008) $\Delta\phi < 0.07$ (0.05)	track iso/ $p_T < 0.125$ (0.125)
VeryTight (VT)	$H/E < 0.05$ (0.05) $\sigma_{inj} < 0.011$ (0.031)			
WP80	$H/E < 0.10$ (0.05) $\sigma_{inj} < 0.01$ (0.03)	ECAL iso/ $E_T < 0.15$ (0.1) HCAL iso/ $E_T < 0.1$ (0.1)	$\Delta\eta < 0.007$ (0.007) $\Delta\phi < 0.06$ (0.03)	track iso/ $p_T < 0.05$ (0.05)

Table 2.1: Naming conventions for electron trigger working points. The given values are for the barrel region of the detector and the values in brackets are for the endcap region.

collection is passed to the cleaning module.

Within CMS, electron and jet collections are reconstructed independently, and since they often leave similar footprints in the detector, these collections can overlap, causing potential double-counting. The electron-jet cleaning module removes electron candidates found by the electron module from the collection of jet candidates found by the jet module. A jet is removed from the jet collection if there is an electron within a cone of $\Delta R = 0.3$ around the jet axis. However, occasionally a genuine jet can be incorrectly identified as an electron. In this case the fake electron can be removed from the jet collection, biasing the performance of the jet multiplicity filter. To tackle this issue, separate jet collections are created for all electrons in the event, where jets are only cleaned from additional (non-signal) electrons. All these jet collections are passed to the following jet multiplicity filter, which accepts an event if at least one collection contains a desired number of cleaned jets.

Electron-plus-jets triggers successfully functioned throughout 2011 and 2012 years of data taking. During 2011, they were used in the top mass analysis and differential cross section analysis with respect to missing transverse energy, described in this thesis. The 2012 cross section analysis used a single electron trigger with a lepton p_T threshold of 27 GeV, reasonably tight (WP80) lepton isolation requirements, but no specific jet requirements. In contrast to 2011 running, this trigger was decided to be unprescaled in the trigger menu for the whole period of data-taking in 2012, regardless of having a significant rate. It is favourable for many analyses as it is much more straightforward in terms of calculating efficiency and acceptance scale factors, also reducing the complexity of estimating the systematic errors associated with the triggering.

2.3 Trigger efficiency measurement

One of the most important characteristics of a trigger path is its efficiency. In a broad sense, selection efficiency can be defined as a conditional probability that a single event passes the selection, given all other conditions (detector configuration, preselection, etc). In the context of the trigger, efficiency highly depends on the offline selection it is measured with respect to. As a matter of fact, different studies can apply different offline selections, therefore the same trigger may have different efficiencies for each of them.

The trigger efficiency can be measured in both data and Monte Carlo simulation using various methods. For all of them, the study has to be performed on some initial preselected dataset. Ideally, this preselection needs to be unbiased with respect to selection imposed by the trigger and offline selection. However, in reality it implies running on vast amounts of data, with very little number of events satisfying the trigger selection, leading to insufficient

statistics or non-feasible computing resources needed for the study. Therefore, some other trigger is used for preselecting the initial dataset, somewhat correlated to the trigger under study in order to obtain reasonable statistics. To correctly measure the efficiency of a trigger path, this correlation has to be taken into account.

The efficiency of a trigger A can be written as the following conditional probability [22]:

$$\epsilon_A = P(A|\vec{x}, T, D) \quad (2.1)$$

where \vec{x} are reference quantities used for triggering (e.g. lepton p_T), and T is an offline selection, and D is a combination of all other factors like detector effects. Assuming that these factors, along with the offline selection and quantities used for triggering are fixed, we can denote $\epsilon_A = P(A)$ for brevity.

If B is the trigger used for preselection, then

$$P(A, B) = P(A|B) \cdot P(B) = P(B|A) \cdot P(A) \quad (2.2)$$

Therefore, as it immediately follows from Bayes' theorem,

$$P(A) = \frac{P(A|B) \cdot P(B)}{P(B|A)} \quad (2.3)$$

Here the conditional probability $P(A|B)$ can be estimated by taking the ratio of the numbers of events that pass the triggers A and B , given that they all pass offline selection. Efficiency of the auxiliary trigger $\epsilon_B = P(B)$ can be estimated from data by using a dataset obtained with looser (“minimum bias”) selection. Unfortunately, conditional probability $P(B|A)$ can not be measured using real data, as by the nature of the study the trigger A only considers events preselected by the trigger B . However, the trigger B is usually chosen in such way that it is safe to assume that $P(B|A) = 1$ with negligible uncertainty. This is the case if the preselection trigger criteria are considerably looser than those of the trigger under study. To summarise, the trigger efficiency can be measured as:

$$\epsilon_A = P(A|B) \cdot P(B) = \frac{N_A}{N_B} \cdot \epsilon_B \quad (2.4)$$

where $N_{A(B)}$ is the number of events that pass the offline selection and fire the trigger A (B).

In case of electron plus jets triggers, the efficiency can be factorised in contributions of

leptonic and hadronic parts of the trigger:

$$\epsilon_{ele+jets} = \epsilon_{ele} \cdot \epsilon_{jets} \quad (2.5)$$

This method can be used under assumption that the probability of finding an electron in the event is independent of the presence of the jets in the event, i.e. leptonic and hadronic “legs” of the trigger are uncorrelated. Although such correlations do exist, it has been shown that most of them are negligible and factorisation method provides a meaningful estimate of the trigger efficiency [23].

Trigger efficiency can be parametrised by various physical quantities of the triggered objects, e.g. reconstructed jet pseudorapidity and transverse momentum. As the background spectrum and trigger rate fall down as a function of jet p_T , trigger efficiency can be described by a turn-on curve approaching a plateau region, where the efficiency is maximum and constant within the statistical uncertainty. It is important for the trigger to have a sharp turn-on, with the nominal 95 % efficiency point being below or approximately at the cut value of offline reconstructed jet p_T . This can be achieved by adjusting the online cuts to be lower than offline ones: if these thresholds are close, then the trigger would bias the analysis distributions. In this case, non-flat p_T -dependent scale factors have to be applied to the total number of signal events, which also complicates estimation of the systematic uncertainty attributed to the trigger. As for the efficiency dependency on the jet angular distribution, it is expected to be flat – however, as it can be seen from the following section, this is not always the case.

2.3.1 Validation of jet energy corrections and charged hadron subtraction for top triggers

In the end of 2011, to match the jet reconstruction method used by most CMS analyses, the calorimeter-based jet module in electron-plus-jets was replaced with PF-based one. This was done in an attempt to improve the p_T resolution of online jet reconstruction, reduce the rate and obtain sharper turn-on curves of the trigger efficiency. In the first iteration of PF-based trigger paths, no jet energy corrections were applied to the jets online, which resulted in observation of a non-flat trigger efficiency with respect to jet pseudorapidity. After a few months of work, responsible physics object group (known as “JetMET”) provided a series of jet energy corrections to be applied at the HLT level, which were tested by the author.

Pile-up turned out to be another major issue particularly specific to 2012 data-taking period. Increased centre-of-mass energy and instantaneous luminosity at a bunch spacing of 50 ns effectively doubled the average number of pile-up vertices comparing to 2011 conditions.

This led to a significant increase in rate of PF-jets triggers, requiring implementation of pile-up mitigation techniques at the HLT level. As a result, charged hadron subtraction (CHS) for PF jets, also known as “PFnoPU”, was introduced online. As the name suggests, it essentially removes the charged hadrons associated with secondary vertices from PF candidates, which helped to reduce the trigger rate dramatically. As top triggers operate with PF jets, they were greatly affected by pile-up, therefore this correction also had to be validated for electron-plus-jets triggers.

In this work, an impact of both jet energy corrections and pile-up subtraction on electron-plus-jets trigger efficiency was investigated. A rather complicated name of the main signal trigger under study (HLT_Ele25_CaloIdVT_CaloIsoT_TrkIdT_TrkIsoT_TriCentralPFJet30) suggests working points of tracker and calorimeter ID and isolation criteria for the signal electron (see Table 2.1), as well as transverse momenta requirements for both electron (25 GeV) and each of the three particle flow jets (30 GeV). Since only hadronic part of the trigger was of interest for this particular study, the efficiency was measured by using a “Single Electron” primary dataset of raw 2012 data. This primary dataset was constructed by accepting events passing at least one of the several single electron triggers with various p_T and isolation requirements. One of the loosest triggers, referred to as HLT_Ele27_WP80, operates with working point “WP80”, also shown in Table 2.1, and electron p_T threshold of 27 GeV.

Offline selection used to obtain a clean $t\bar{t}$ sample is outlined in Section [?], with an exception of the jet multiplicity requirement: here at least three jets were required. A tighter requirement of at least four jets was also of interest, as described below. The trigger efficiency is then calculated as:

$$\epsilon = \frac{N_{\text{fired}}}{N_{\text{selected}}} \quad (2.6)$$

where N_{selected} is the number of events from the primary dataset passing the described offline selection, and N_{fired} is the number of events which in addition fired the electron plus three jet trigger.

All the efficiencies were measured in bins of jet p_T and η . For these variables, different fit functions were used. The efficiency in p_T was fitted with the default function describing the turn-on curve:

$$\epsilon(p_T) = A \times e^{(B \times e^{C \times p_T})} \quad (2.7)$$

while the efficiency in η was fitted with

$$\epsilon(\eta) = A \times \eta^2 + B \times \eta + C \quad (2.8)$$

where A , B and C are the fit parameters.

Although the η dependency was expected to be flat, the observed structure in the η distribution of the PF jet triggers suggested the use of a parabolic fit function. In fact, this drop of the efficiency in the endcap region was the main motivation for the study, as it was believed to be due to the fact that the p_T - and η -dependent jet energy corrections were not applied online, causing inconsistency between HLT and offline reconstructed jets. Efficiency of the main electron-plus-jets trigger with no jet energy corrections applied is shown on Figure 2.2. Clearly, parabolic shape is seen on the efficiency plot with respect to pseudorapidity of a third reconstructed jet (all the jets were sorted by the value of transverse momentum).

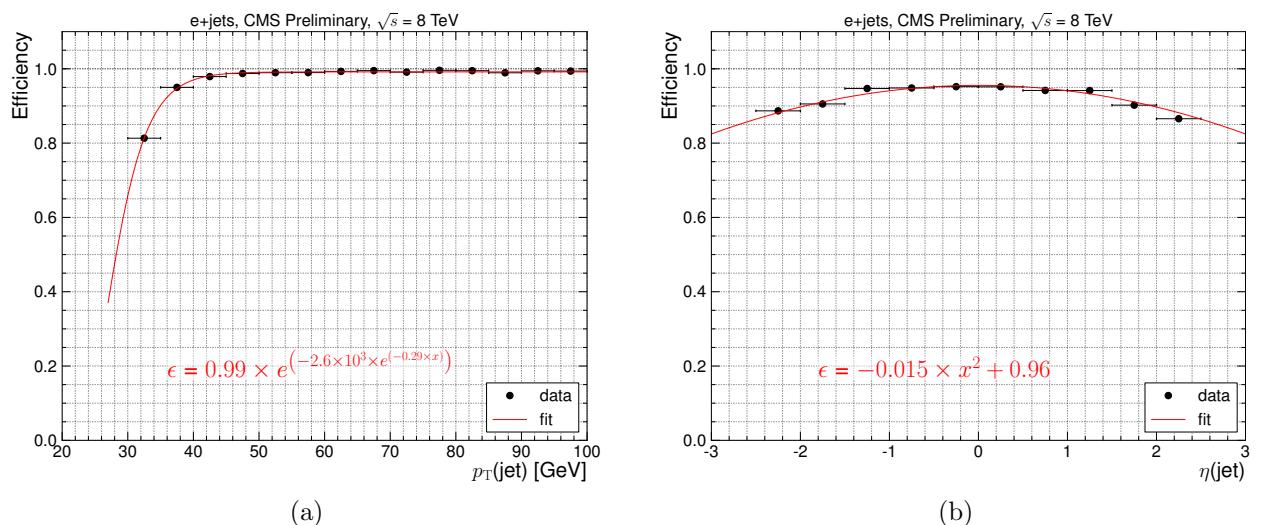

Figure 2.2: Trigger efficiency for HLT_Ele25_CaloIdVT_CaloIsoT_TrkIdT_TrkIsoT_TriCentralPFJet30 (uncorrected) as a function of jet p_T (a) and η (b) for events with at least three jets

It has to be emphasised that only efficiencies with respect to offline selection with at least three jets were affected. Requiring a fourth jet in the event increases the trigger efficiency to nearly 100 %, as it can be seen on Figure 2.3. This implies that observed inefficiency in the endcap region was not critical for analyses requiring at least four jets in the event (including the ones in this thesis), however, it was still important to investigate this effect in order to better understand any possible systematic errors due to the triggering.

For the purpose of the study, a modified HLT menu was created, containing new versions of the main signal trigger with jet energy corrections and charged hadron subtraction applied. This menu was run on a $t\bar{t}$ skim of a RAW dataset mentioned above, and resulting trigger

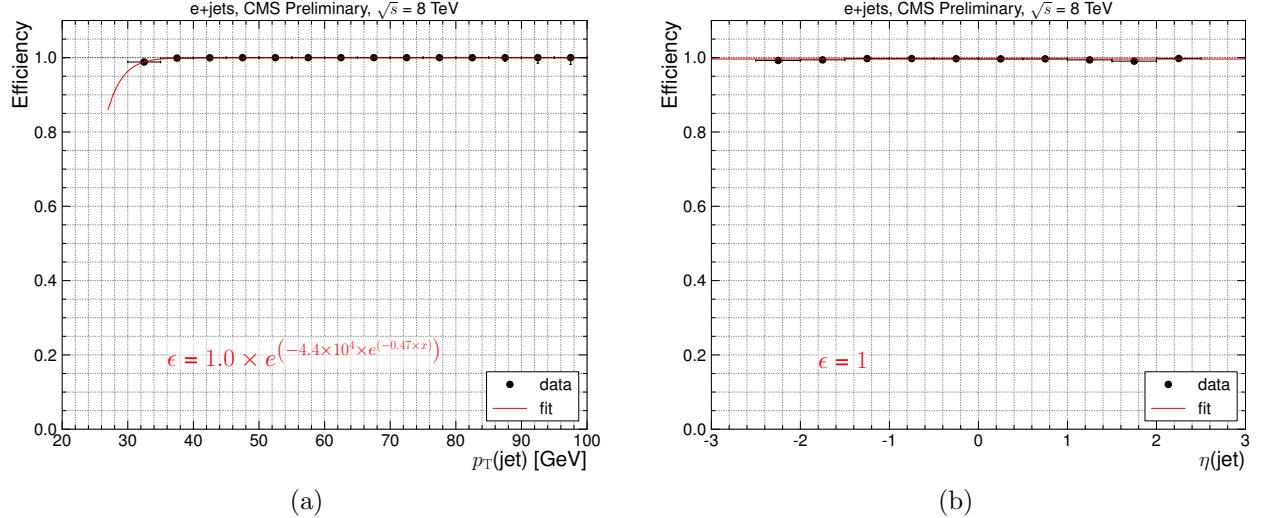

Figure 2.3: Trigger efficiency for HLT_Ele25_CaloIdVT_CaloIsoT_TrkIdT_TrkIsoT_TriCentralPFJet30 (uncorrected) as a function of jet p_T (a) and η (b) for events with at least four jets

flags as well as jet collections were used to produce the final plots.

Figure 2.4 presents the results for the aforementioned trigger path but with jet energy corrections applied, and Figure 2.5 shows it for the same path with both charged hadron subtraction and jet corrections applied. It is obvious that all these corrections haven't solved the inefficiency problem in the endcaps, which caused some confusion in the group that provided them and triggered additional scrutiny from the trigger and jet/ E_T^{miss} experts.

In order to gain further understanding, jet response distributions were investigated. Jet response is a ratio of the transverse momenta of offline-reconstructed and HLT jets, ideally produced from the same objects in the detector. To find this ratio, all the HLT jets were matched with offline jets found within a cone of $\Delta R = 0.3$ for each online jet. Matching efficiency proved to be close to unity, and following distributions were produced only for the successfully matched jets. Figure 2.6 shows the response plots for trigger paths with different corrections: uncorrected, only jet energy corrected (JEC) and with both jet energy corrections and charged hadron subtraction (JEC+CHS) applied. It can be seen that corrections work reasonably well in the barrel region, but substantially underestimate the energy of online jets in the endcap region. The response plot shown in slices of offline jet transverse momenta (c) suggests that corrections work better for jets with higher energy, which can also be seen from the distribution with respect to jet p_T , however, the overall response in the endcap region is still far from being perfect.

Figure 2.4: Trigger efficiency for HLT_Ele25_CaloIdVT_CaloIsoT_TrkIdT_TrkIsoT_TriCentralPFJet30 with jet energy corrections applied online, as a function of jet p_T (a) and η (b) for events with at least three jets

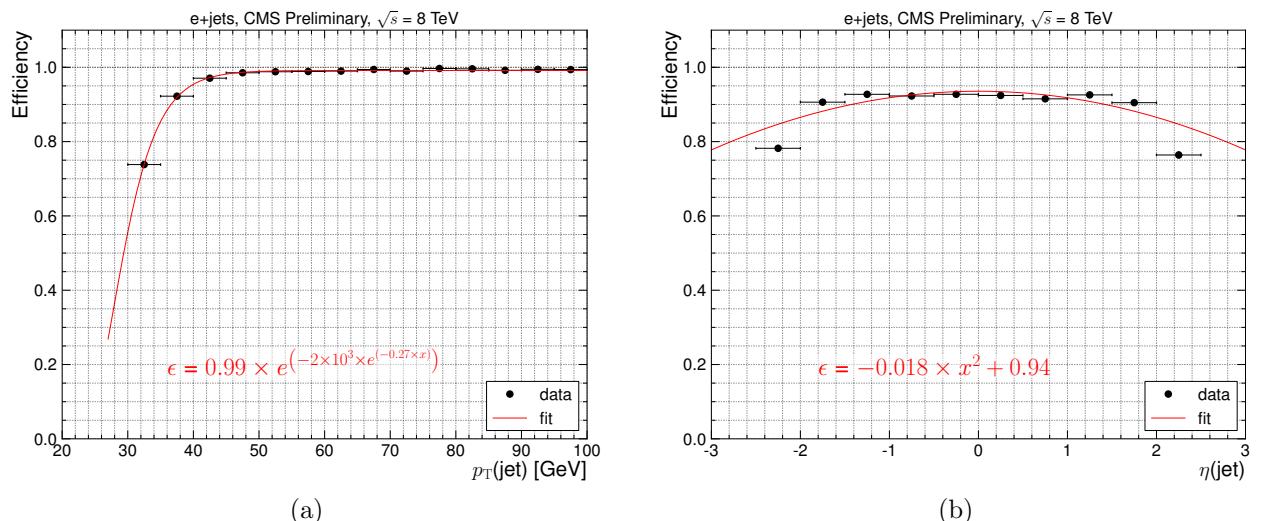

Figure 2.5: Trigger efficiency for HLT_Ele25_CaloIdVT_CaloIsoT_TrkIdT_TrkIsoT_TriCentralPFJet30 with jet energy corrections and charged hadron subtraction applied online, as a function of jet p_T (a) and η (b) for events with at least three jets

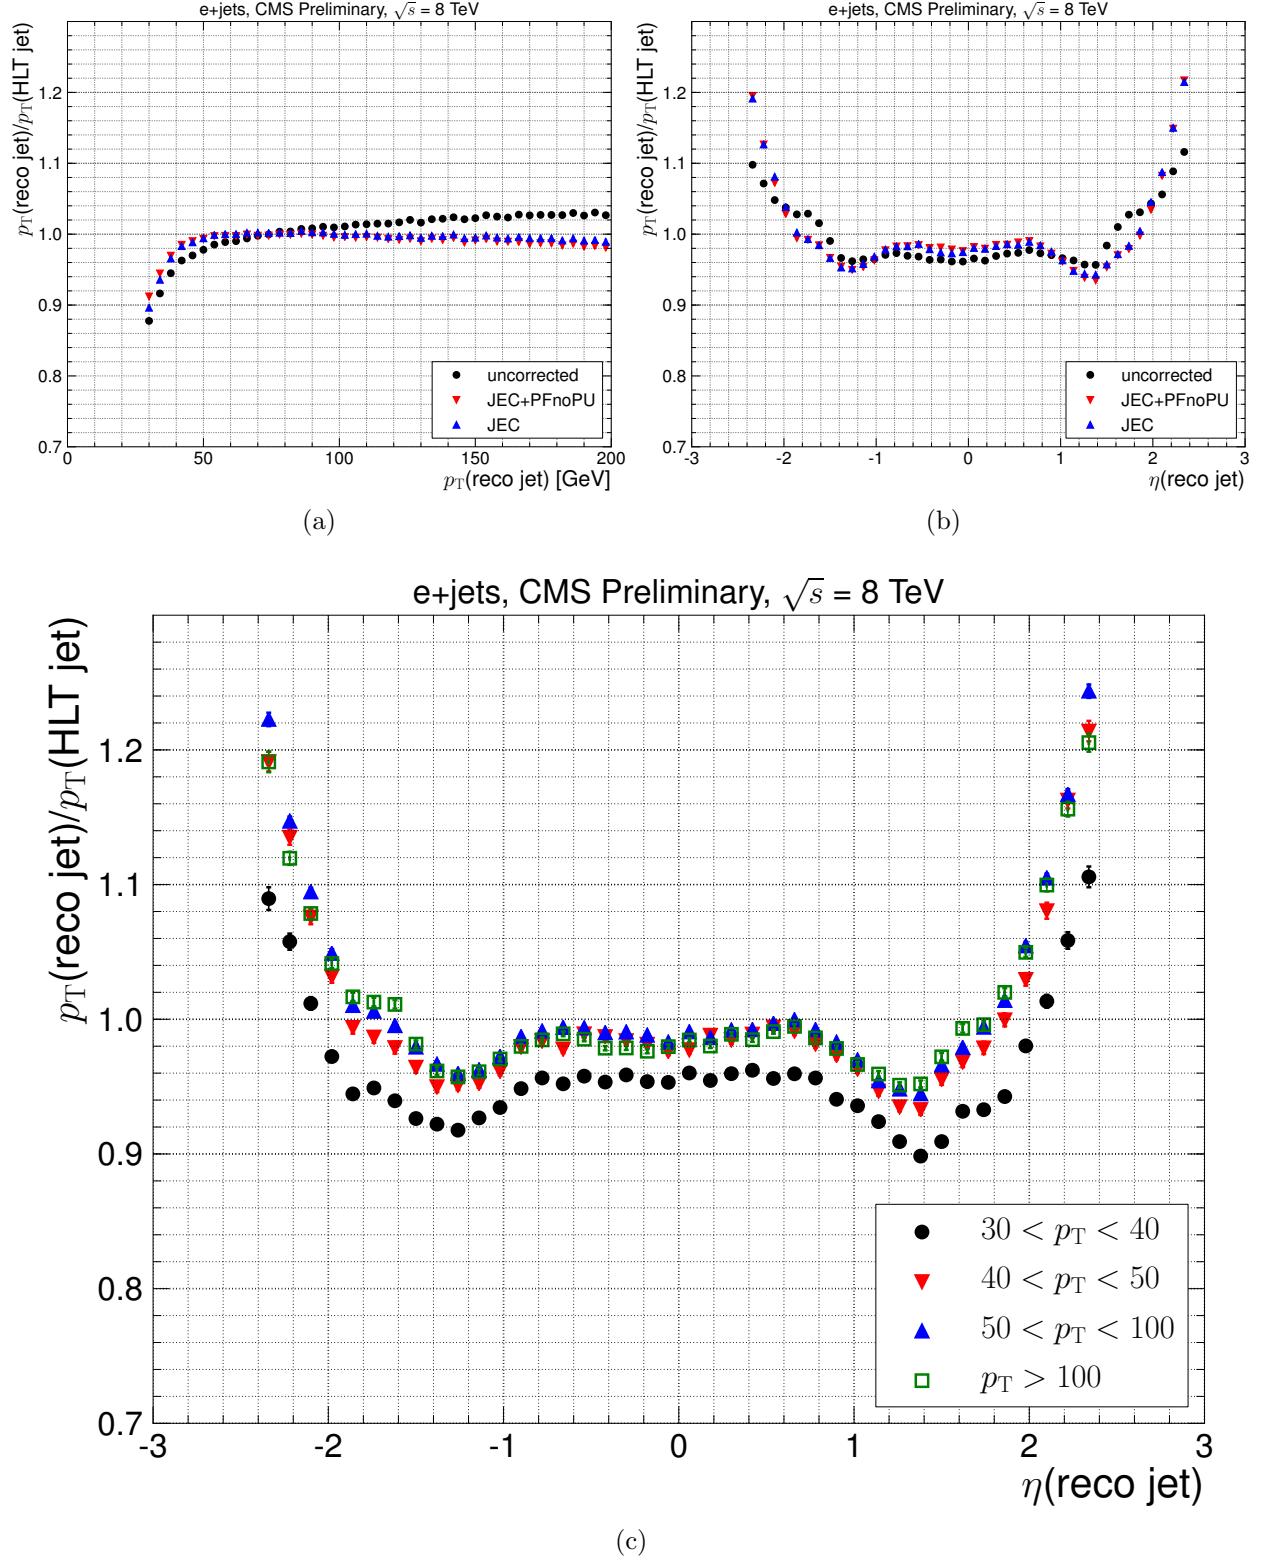

Figure 2.6: Ratio of matched offline and online reconstructed jet transverse momenta as a function of offline jet p_T (a) and η (b) for different jet corrections and in slices of offline jet p_T (c)

Shortly after these results were presented to the trigger coordination, they were confirmed independently by other experts within the JetMET group. Because of the time constraints associated with the luminosity increase schedule, a following workaround solution was suggested. In order to re-gain the trigger efficiency, the threshold for the third jet was dropped from 30 GeV to 20 GeV, which allowed to apply jet energy corrections and charged hadron subtraction with a minimum loss in the efficiency in the endcap region. However, this was a subject of a different study.

2.4 Summary

This chapter covered the service work performed by the author for CMS collaboration, namely development, validation and maintenance of high-level triggers for top quark physics, specifically for the electron channel of semi-leptonic $t\bar{t}$ decay signature. The importance and typical challenges of trigger development has been discussed. The modular structure of high level triggers has been described in detail for electron-plus-jets paths. A core of author's contribution: the investigation of the effect of jet energy corrections applied on the HLT level to top trigger paths has been presented, showing how it affects trigger efficiency and jet response distributions. An impact of charged hadron subtraction applied online has also been studied and demonstrated.

3.2 Event Selection

3.3 Kinematic Fit

3.4 Ideogram Method

3.4.1 Event likelihood

3.4.2 Combined likelihood fit

3.5 Mass calibration

3.6 Systematic Uncertainties

3.7 Results

3.8 Summary
